A great deal of confusion and potential litigation can be mitigated by thorough analysis, intervention, and documentation (Box 85-1). Primary care physicians should document in the newborn's medical record the reasons for which they are attending the delivery, summarize the risks as known to them, and indicate what interventions were initiated and the newborn's response to these interventions. Was the infant delivered by cesarean section? If so, was there an indication such as suspected placental abruption? What is the estimated gestation? Was the mother febrile? How long have the membranes been ruptured? Was the mother treated with antibiotics before delivery? Does other salient maternal medical information exist that may affect the newborn or the resuscitative measures that might be necessary? What was the condition of the newborn at birth? What were the assessments, and what treatments were initiated? How did the infant respond to these interventions? It is also important that the infant be appropriately monitored after resuscitation. If an infant requires positive pressure ventilation, the NRP recommends that the infant be transferred to a place of "continuing observation." This does not necessarily mean the neonatal intensive care unit (NICU), but it should be a monitored area of the nursery.

### BOX 85-1 Strategies to Minimize Delivery Room Risk

- Maintain resuscitation skills; stay current according to the NRP guidelines.
- Know the capabilities of the other members of the resuscitation team.
- Know the capabilities of the facility.
- Document the situation, interventions, responses, and communications.
- Participate in team-based training and simulation activities that foster communication, skill building, and teamwork.

Other professionals may be in the delivery room to assist with airway management. An anesthesiologist or nurse anesthetist may be able to assist if a particular intubation is problematic. Even though the anesthesiologist's primary responsibility is the newborn's mother, fellow professionals often are willing to assist, so long as it does not mean jeopardizing their primary patient. Resuscitation is a team effort, and it is important that duties be defined before the delivery. Team training and debriefing can help to improve communication skills among team members. Debriefing and discussion after a delivery may ensure that families are given consistent information.

Primary care physicians may have their first interaction with a family in the delivery room. The pediatrician who has had prior contact with the family can bring considerable comfort to the family. Without this prior contact, the pediatrician should attempt to establish rapport with the family. Although parent (family)–professional communication under this circumstance can be quite difficult, it is nonetheless critical to helping parents understand the physician's concerns for the newborn and engaging the parents in medical decision-making plans for the newborn regarding ongoing evaluation and treatment. This factor is particularly important if the resuscitative efforts are not successful, in specific cases in which a problem was not anticipated before the newborn's delivery, and when a neonate requires transfer to another facility for care that is unavailable at the birth hospital.

## MEDICAL-LEGAL CONSIDERATIONS IN THE HEALTHY NEWBORN NURSERY

One of the more challenging aspects of general pediatric practice is determining which newborns are well and which ones are sick. The differential diagnosis and initial management of a newborn can be challenging for a seasoned neonatologist or hospital-based pediatrician with years of delivery room and newborn nursery experience who has the benefit of direct observation. Primary care physicians are often at a significant disadvantage because they may not be present in the nursery when a concern arises and receive a call from the nursery nurse or family relaying symptoms. A common factor that poses a liability risk for the health professional involves failure to diagnose a condition for which early diagnosis and treatment may prevent death or long-term morbidity. Among the risks are missed diagnoses of clinically significant congenital heart disease (eg, ductus-dependent cardiac lesions), detection of birth defects that result in early neonatal illness (eg, gastrointestinal or genitourinary obstruction, congenital hydrocephalus) or require timely intervention (eg, congenital glaucoma, retinoblastoma, developmental dysplasia of the hip), suspected brachial plexus injuries or birth trauma and injury that may result in cerebral palsy and brain damage, congenital conditions that may be detected through newborn screening (eg, for hearing loss), hyperbilirubinemia leading to kernicterus, signs and symptoms of hypoglycemia, infection, and seizures. Nurseries should implement oxygen saturation screening to detect cyanotic heart disease as recommended by the AAP. Failure to follow up on prenatal

information that suggests a potential health risk for the infant is an important issue as well. The use of prenatal ultrasonography, although not necessarily an American College of Obstetrics and Gynecology (ACOG) standard of care, has become a routine component of prenatal care nationwide. As a result, many infants are identified prenatally as having a suspected congenital anomaly. The severity of the anomaly will determine the level of hospital in which the infant should be delivered. A high index of suspicion and appropriate follow through may help to prevent an adverse outcome.

Detailed discussion of these problems is contained in subsequent chapters in this section of the text. Appropriate counseling of the family is important, as is early postnursery follow-up care, to assess the infant's continued postnatal adaptation, evaluate for other signs or symptoms, and address parental concerns. The pediatric professional should also work with the nursery staff to ensure that home or public health nurse visits are coordinated, if covered by the family's insurance, to assist the family with the transition home and to provide an objective, interim assessment of the newborn until the first follow-up office visit with the PCP. If this service is not available, then consideration should be given to an earlier follow-up appointment. Physicians should comply with AAP guidelines regarding follow-up appointments for newborns after discharge from the hospital. It is also essential that the physician-led team assess for any barriers to adherence to recommended care and follow-up visits as required (eg, transportation, child care, language or communication, health insurance, access to primary and specialty care). Physician documentation in the newborn's medical record of the clinical concerns, available and pending test results, recommended plan of care, and content of discussions with the family, which includes their concerns, their understanding of their child's issues, and their expressed barriers to complying with the recommended care, can help reduce liability risks. Ideally, discharge instructions that are given to the parents should also be documented in the medical record.

## MEDICAL-LEGAL CONSIDERATIONS IN CARING FOR SICK NEWBORNS

Before PCPs provide care for sick newborns, they must pay close attention to their hospital's policies. Some nurseries will take care of healthy newborns only. If an infant requires supplemental oxygen beyond a defined period (perhaps >4 hours), positive pressure ventilation, or ventilator assistance, then the baby must often be transferred to an affiliated hospital that can provide the scope of care required. Regionalized perinatal care varies throughout the United States. Regional perinatal centers are typically state health department-designated tertiary care facilities that are capable of caring for the sickest and most medically complex women and infants. Within communities, affiliation agreements will exist between the regional center and community hospitals that are able to provide varying levels of high-risk care to pregnant women and sick or premature infants. These relationships are often codified in individual state public health law statutes. The AAP and ACOG *Guidelines for*

*Perinatal Care* are updated regularly and specify the requirements in facilities, personnel, expertise, and equipment for the level (scope) of care a hospital provides.

Four levels of care have been delineated: basic care (level I; routine maternity and newborn care to low-risk infants and women), specialty care (level II; obstetric and newborn services to care for patients with specific high-risk conditions exclusive of the most critically ill, medically complex, and premature infants), and subspecialty care (levels III and IV; the full range of medical care to the most medically complex women and infants). In many states, subspecialty care facilities, or level IV perinatal centers, also serve as regional perinatal centers with quality assurance, education, and outreach responsibilities. However, some states have a plethora of level III facilities, with a smaller number designated as level IV regional perinatal centers in recognition of their unique role in providing the most comprehensive treatments in addition to care coordination, education, outreach, and quality improvement activities. The AAP has a policy statement outlining a uniform definition for levels of care (see Box 85-2).

In many community newborn nurseries, the requirement for intravenous antibiotics will necessitate a transfer to another facility. Within larger hospitals or select institutions that are equipped to provide a broader spectrum of newborn care, transfer to another facility may not be necessary; instead, the newborn may be transferred to a special care nursery or an NICU. Interhospital and regional perinatal affiliation

agreements guide transfer relationships and the level of care required for particular maternal or newborn care issues. In addition to the pediatric care, physician's experience, and degree of comfort in caring for newborns with a variety of medical problems, hospitals have guidelines that delineate the privileges of its physicians and the scope of care that they may provide.

## MEDICAL-LEGAL ISSUES RELATED TO SPECIFIC NEWBORN CONDITIONS

A PCP often supervises the care of a neonate who requires a higher level of care for a single organ system. Perhaps the newborn has hypoglycemia, requires antibiotics, or requires supplemental oxygen for a brief period. Although many PCPs would choose to transfer these infants to a neonatologist, other PCPs are quite comfortable caring for sick newborns in a specialty or level II neonatal unit. Under certain circumstances, a pediatrician may need to care for a very sick baby until the perinatal center's transport team arrives. These clinicians may need to provide ongoing stabilization care, place umbilical lines, and supervise mechanical ventilation for brief periods. In general, most newborns who require prolonged ventilation (>4–6 hours) or support for more than one organ system will be transferred to the care of a neonatologist.

Several common neonatal medical problems pose an increased liability risk for the PCP because of the potential for long-term sequelae and associated morbidities.

### BOX 85-2 AAP Proposed Uniform Definitions for Capabilities Associated With the Highest Level of Neonatal Care Within an Institution

#### Level I neonatal care (well-born nursery) has the capabilities to:

- Provide neonatal resuscitation at every delivery
- Evaluate and provide postnatal care to stable term newborn infants
- Stabilize and provide care for infants born at 35 to 37 wk gestation who remain physiologically stable
- Stabilize newborn infants who are ill and those born at <35 wk gestation until transfer to a facility providing the appropriate level of neonatal care

#### Level II neonatal care (special care nursery) has Level I capabilities plus:

- Provide care for infants born  $\geq 32$  wk gestation and weighing  $\geq 1,500$  g who have physiologic immaturity or who are moderately ill with problems that are expected to resolve rapidly and are not anticipated to need subspecialty services on an urgent basis
  - Provide care for infants convalescing after intensive care
  - Provide mechanical ventilation for brief duration (<24 h) or continuous positive airway pressure or both
- Stabilize infants born <32 wk gestation and weighing <1,500 g until transfer to a neonatal facility

#### Level III neonatal care (NICU) has Level II capabilities plus:

- Provide sustained life support
- Provide comprehensive care for infants born and weighing intensive care <32 wk gestation and weighing <1500 g and infants born at all gestational ages and birth weights with critical illness
- Provide prompt and readily available access to a full range of pediatric medical subspecialists, pediatric surgical specialists, pediatric anesthesiologists, and pediatric ophthalmologists
- Provide a full range of respiratory support that may include conventional and/or high-frequency ventilation and inhaled nitric oxide
- Perform advanced imaging, with interpretation on an urgent basis, including computed tomography, MRI, and echocardiography

#### Level IV neonatal care (regional NICU) has Level III capabilities plus:

- Located within an institution with the capability to provide surgical repair of complex congenital or acquired conditions
- Maintain a full range of pediatric medical subspecialists, pediatric surgical subspecialists, and pediatric anesthesiologists at the site
- Facilitate transport and provide outreach education

## Hypoglycemia

Transient low serum glucose is a common issue in newborns. Primary care clinicians are regularly consulted about newborns with hypoglycemia. Knowledge about the risk factors that predispose a newborn to the development of hypoglycemia and the normal physiologic changes in energy metabolism and glucose utilization occurring after birth prepare the pediatrician to recognize, appropriately evaluate, and manage the newborn with low blood sugar. One of the challenges facing the pediatrician is the lack of a single, uniform definition of hypoglycemia and the influence of gestational and postnatal age in setting a threshold to define *clinically significant hypoglycemia*. Most nurseries have established patient care policies that detail which infants should be screened for low blood sugar, the frequency of testing, and guidance regarding assessment, feeding, and intervention strategies. Studies reporting on the neurodevelopmental outcome of babies who develop symptomatic hypoglycemia have reported conflicting results. A recent systematic review did not produce conclusive recommendations for clinical practice in the care of neonates experiencing hypoglycemia in the first week of life because of a paucity of quality studies and heterogeneity among the patients included in the reported studies. Among healthy, full-term newborns, transient, mild neonatal hypoglycemia has not been shown to affect later neurodevelopment. In 2011, the AAP issued a clinical report that included an algorithm for the screening and subsequent management of neonatal hypoglycemia that includes which infants to screen, when to screen, laboratory data, clinical signs, and management.

The pediatrician should recognize that failure to identify, evaluate, and treat infants at risk for or exhibiting symptoms potentially caused by hypoglycemia and failure to document the rationale for treatment or nontreatment may be a cause for later litigation if the child develops subsequent neurodevelopmental problems. For newborns experiencing clinically significant episodes of hypoglycemia, the full extent of neurologic injury may not be fully recognized for decades. Being aware of the admitting nursery's policies and documenting identified risk factors, glucose screening (and any confirmatory testing) results, and response to feeding or other interventions initiated are important. Communication with the nursery staff and the family is of paramount importance.

## Perinatal Event

Cerebral palsy (CP) is the most common injury claimed as a result of obstetric or neonatal negligence. Frequent causes cited to account for the development of CP include intrapartum or postpartum asphyxia, birth trauma, brain injury caused by intracranial hemorrhage or ischemia, peripartum infection, kernicterus, and hypoglycemia. Injury may result from chronic, subacute, or intermittent hypoxic-ischemic episodes or acute intrapartum events that may occur at various times during gestation, including the antenatal or immediate peripartum period. Substantial in utero injury can also precede the onset of labor. A relatively common occurrence during labor is an *indeterminate*

or *category II fetal heart rate tracing*, previously referred to as a *nonreassuring fetal monitoring strip*. A problematic monitoring strip can be associated with a variety of in utero issues. Fetal head compression, uteroplacental insufficiency, placental abruption, and other events may be reflected in the fetal monitoring strip. That only 12% to 23% of cases of CP diagnosed in term infants were caused by intrapartum or peripartum events has been well described.

From a legal standpoint, the statute of limitations (SOL) can last decades. This means that in many states, a family can file suit against the obstetrician or pediatrician when the child is of college age. Within this context, the test for SOL is generally when a reasonable plaintiff might have discovered the abnormality if they had investigated. In case of neonatal encephalopathy, the full extent of the injuries may not be clear for decades, which is one of the reasons that the SOL can extend so many years in these cases.

A variety of medical issues need to be considered when an infant is born with suspected encephalopathy. Will the infant develop seizures? Was the mesenteric blood flow compromised? If so, then how long should the physician wait before the initiation of enteral feeds? Is the infant at risk for renal or other organ dysfunction? The pediatrician is well advised to consult with a neonatologist about any newborn who is born after a high-risk delivery. Many of these cases result in malpractice litigation. The care provided by the pediatrician will likely be highly scrutinized. Did the neonate sustain additional injury after birth? Was the pediatrician's care contributory to this additional injury? Maintaining good communication with the family is particularly important in these cases. Minimally, the pediatrician should document the consultation with the family, the consultation with the neonatologist, the assessment, and the plan. Making promises to the family concerning outcome is generally not advised, given that many years may pass before the outcome is completely understood. Therefore, any assurances to the family will be based on incomplete information.

The timing of a suspected perinatal event sufficient to cause CP remains an issue of contention. The ACOG and AAP have published criteria to define an acute intrapartum hypoxic event as sufficient to cause cerebral palsy (Box 85-3).

Primary care physicians should exercise care in their medical documentation and refrain from using the term *perinatal asphyxia* unless appropriate criteria exist to support using this term. Although numerous markers of intrapartum asphyxial injury have been identified, no single marker is diagnostic.

Therapeutic hypothermia for the prevention or reduction of perinatal brain injury provided as head cooling or total body cooling has become the standard practice in many regions of the country. Because the current data indicate that the newborn who experiences a moderate degree of encephalopathy will derive maximal benefit if cooling is initiated within 6 hours of birth, the pediatrician must maintain a high index of suspicion for hypoxic-ischemic encephalopathy (HIE). If HIE is suspected, the pediatrician

### BOX 85-3 AAP/ACOG Criteria to Define an Acute Intrapartum Hypoxic Event as Sufficient to Cause Cerebral Palsy

- |  |   |
|--|---|
| <p>1.1: Essential Criteria (must meet all 4)</p> <ol style="list-style-type: none"> <li>1. Evidence of a metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH &lt;7 and base deficit <math>\geq 12</math> mmol/L)</li> <li>2. Early onset of severe or moderate neonatal encephalopathy in infants born at <math>\geq 34</math> weeks' gestation</li> <li>3. Cerebral palsy of the spastic quadriplegic or dyskinetic type</li> <li>4. Exclusion of other identifiable etiologies, such as trauma, coagulation disorders, infectious conditions, or genetic disorders</li> </ol> <p>1.2: Criteria that collectively suggest an intrapartum timing (within close proximity to labor and delivery,</p> | <p>eg, 0–48 hours) but that are nonspecific to asphyxial insults</p> <ol style="list-style-type: none"> <li>1. A sentinel (signal) hypoxic event occurring immediately before or during labor</li> <li>2. A sudden and sustained fetal bradycardia or the absence of fetal heart rate variability in the presence of persistent, late, or variable decelerations, usually after a hypoxic sentinel event when the pattern was previously normal</li> <li>3. Apgar scores of 0–3 beyond 5 minutes</li> <li>4. Onset of multisystem involvement within 72 hours of birth</li> <li>5. Early imaging study showing evidence of acute nonfocal cerebral abnormality</li> </ol> |

should consider immediate consultation with an NICU that provides cooling.

#### Role of Umbilical Cord Blood Gases

Within the obstetric and risk management communities, there is an increasing emphasis on the role of umbilical arterial cord blood gas base deficit in timing fetal hypoxic injury. Umbilical arterial or venous blood gases or an early neonatal arterial base deficit (before significant correction of respiratory acidosis or administration of fluid boluses or bicarbonate) may reflect the level of acidosis at the time of delivery. Increasingly, as part of their quality improvement and risk management programs, hospital obstetric services are implementing protocols by which umbilical arterial cord blood gases are routinely obtained for all deliveries (see Chapter 109, Assessment and Stabilization at Delivery). It is important to recognize that impaired cord blood flow (as with an occluded cord) may provide invalid cord gas results. Additionally, even among newborns exhibiting severe encephalopathy, less than 25% of cases are attributable to fetal hypoxemia. After vaginal delivery, the normal mean umbilical arterial base deficit is 4 to 5 mmol/L (if base excess is reported, then the respective values are  $-4$  to  $-5$  mmol/L). The degree of metabolic acidosis that determines the threshold for injury is generally defined as greater than 2 standard deviations from the mean (10–12 mmol/L) and is accepted as greater than 12 mmol/L. Base deficit levels exceeding 12 mmol/L occur in less than 2% of a normal newborn population. Of note, most newborns with a base deficit above 12 mmol/L do not demonstrate long-term neurologic injury. Among newborns experiencing severe metabolic acidosis with base deficits above 16 mmol/L, most die, or if they survive, are healthy.

#### Seizures

A pediatrician may occasionally be notified that a newborn is suspected of having had a seizure. Additionally, apnea in a term baby should be investigated as

a potential seizure. Although a neonatal seizure will often place the newborn outside of the scope of general pediatric care, the pediatrician may be required to provide the initial evaluation and stabilization. Although many infants will continue to breathe during a seizure, the physician should always keep in mind the ABCs (airway, breathing, and circulation). If the newborn does not require airway management or circulatory support, then the pediatrician may give the newborn antiseizure medications. What are the complications of these drugs? Is phenobarbital the first-line drug? If the pediatrician is ordering these medications, then the potential complications, including apnea, should be considered. Incorrect dosing is a potential source of medication error; attention also needs to be paid to the medication order (loading dose or maintenance therapy), route of administration, and dosing interval. Is the seizure a result of HIE, infection, hypocalcemia, or a brain malformation? Is the neonate hypoglycemic? The prudent PCP will deal with the immediate medical needs of the newborn and promptly consult with a pediatric neurologist, a neonatologist, or both. Beyond immediate stabilization, rarely does a general pediatrician provide continuing care for a neonate with seizures in the immediate neonatal period.

#### Brachial Plexus Injuries

Brachial plexus injury (BPI) is relatively common in neonates, with a reported incidence of clinically significant lesions occurring at a rate of 0.5 to 2.6 per 1,000 live births. Not all BPIs are the result of birth-related trauma; intrauterine malpositioning has also been implicated, especially given that BPI has been documented among healthy newborns born atraumatically by cesarean delivery. A BPI is nonetheless an important cause of malpractice litigation against medical caregivers and therapists. The PIAA reports that nearly 60% of BPI malpractice claims result in monetary damages. Litigation may also result from a failure of the pediatric care physician to recognize medical

**BOX 85-4 Potential Sources of Liability Related to Severe Hyperbilirubinemia and Kernicterus**

- Early discharge
- Not recognizing that bilirubin is rising at the time of discharge
- Failure to educate parents about the dangers of jaundice
- Failure to ensure targeted follow-up after nursery discharge
- Failure to treat a newborn with a TSB or TcB in the high-risk zone
- Failure to recognize the severity of hyperbilirubinemia corrected for age in hours, not days, of life (Bhutani curve)
- Failure to recognize risk factors, such as blood group incompatibility, positive Coombs test, excessive bruising, cephalohematoma, family history of G6PD deficiency, East Asian ancestry, possible sepsis, prematurity, exclusive breastfeeding with evidence of excess weight loss/inadequate feeding skills
- Delay in timely or intensive intervention predischARGE or at readmission
- Not recognizing the inaccuracies of visual assessment of jaundice
- Not responding appropriately to parental concerns about jaundice, poor feeding, or changes in infant behavior

G6PD, glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin; TSB, total serum bilirubin.

conditions associated with BPI. These conditions include diaphragmatic paralysis, cervical spine injury, facial paralysis, vocal cord paralysis, shoulder subluxation, and unilateral clavicular and humeral fractures. Therefore, the newborn suspected of having a BPI should have a thorough physical examination and radiographic studies to evaluate the clavicle and humerus on the involved side. Physical findings will guide the need for other studies. In general, the pediatrician should carefully document normal and symmetrical extremity movement and limb posture or position on the initial physical assessment and again at the time of nursery discharge.

Prognosis for recovery in BPI is typically associated with the severity of the infant's motor deficit. Infants who have moderate motor dysfunction at the time of presentation are less likely to have significant permanent weakness than infants with severe motor dysfunction. The period of recovery may continue for up to a year; however, most infants with milder injuries recover within the first few weeks. A recent meta-analysis found that 20% to 30% of infants who have BPI will have residual neurologic deficits. The provision and timing of initiation of treatment are also important considerations and may contribute to parents' decision to initiate a claim. Initial therapy typically involves a period of immobilization to allow for resolution of edema. This therapy is followed by careful passive range-of-motion exercises to prevent contractures and muscle atrophy. Infants who are not improving by 3 to 6 months of age should be referred for further evaluation (electromyographic assessment and neurosurgery for possible nerve transplantation).

Communication between the health professionals and child's parents is critical and can be an effective risk management tool when the physician uses a proactive approach.

- The pediatrician should not assume that all BPIs are the result of birth trauma.
- Family history should be explored if the suspected BPI cannot be explained based on a difficult delivery or intrauterine malpositioning.
- Neonates with suspected BPI should be evaluated for associated conditions.

- Physical assessments should document extremity posture, position, movement, and symmetry.
- Parents should be informed about the range of recovery possible and that long-term sequela may result from the BPI.
- Close follow-up care is important, including appropriate consultations with a pediatric neurologist and a physiatrist, as well as early intervention referrals as appropriate based on state-specific eligibility requirements.

**Hyperbilirubinemia**

Sixty percent of newborns develop clinical jaundice. (See Chapter 99, Neonatal Jaundice, and 170, Jaundice, for discussion on Jaundice.) Consequently, most PCPs treat newborns with elevated serum levels of indirect (unconjugated) bilirubin. The complications of hyperbilirubinemia have been well described. Cases in which an infant is diagnosed with kernicterus often result in multimillion-dollar legal settlements. In April 2001, the Joint Commission for the Accreditation of Healthcare Organizations (now known as the Joint Commission) issued a sentinel alert about the threat posed by kernicterus, a generally preventable condition, to healthy newborns. In the most severe cases, the newborn can sustain permanent neurologic injury or even death. Box 85-4 summarizes the factors that contribute to the risk for severe hyperbilirubinemia and kernicterus. Any of these factors can warrant more aggressive treatment of hyperbilirubinemia.

A recent publication by Beal and associates highlights an increasing challenge confronting physicians who must identify and treat conditions that typically occur in higher frequencies in specific ethnic groups—the increasing number of multiethnic infants born. In this study conducted at the Henry Ford Health System, a major urban medical center serving a large minority population, the investigators found that racial identification in medical records did not completely overlap with the mother's self-report of her infant's race. When given the opportunity to select more than one race for their child, 41% of mothers of interracial infants described their infants as having

other racial ancestry in addition to that of the mother and father. Therefore, the pediatrician should consider exploring the ancestry of a newborn who exhibits clinical symptoms of a condition not common for the child's perceived race or ethnicity.

Another important cause of neonatal hyperbilirubinemia is glucose-6-phosphate dehydrogenase (G6PD) deficiency. Diverse population groups are affected by G6PD deficiency caused by many gene polymorphisms that result in decreased bilirubin conjugation. Population migration has contributed to a worldwide distribution of babies born with hyperbilirubinemia caused by G6PD deficiency. Black newborns are the largest population group affected by G6PD deficiency in North America. There have been case reports of kernicterus caused by severe hyperbilirubinemia in black G6PD-deficient newborns. G6PD deficiency is an X-linked condition and is less frequently considered to be a causative factor in newborn girls with hyperbilirubinemia. However, G6PD-deficient heterozygote girls have been identified, and their neonatal course may be complicated by hyperbilirubinemia.

Hyperbilirubinemia is common, and the pediatrician should remain current with the literature on this topic. If a particular newborn's course is complicated by serum levels that are increasing quickly, as indicated by inadequate response to phototherapy, hemolysis, anemia, altered neurologic examination or mental status, or other significant finding, then the pediatrician should strongly consider consultation with a neonatologist. The management of these cases can be complex, and the potential for liability is extremely high. If a newborn suffers a severe complication of hyperbilirubinemia, then the pediatrician's treatment will likely be scrutinized. How often were bilirubin levels checked? How quickly was therapy instituted? Was a consultation with a neonatologist obtained? The care and treatment of newborns with severe hyperbilirubinemia can lead to litigation, and both the infant and the pediatrician will likely benefit from the input from a neonatologist. The key to protecting the pediatrician and ensuring optimal care for the newborn is risk assessment, with performance of systematic assessments on all newborns before nursery discharge. Nursery protocols should integrate bilirubin measurement, risk factor identification, and appropriate follow-up. If a parent calls the office and is worried that the infant is jaundiced, the infant should be seen in a timely manner.

### **Late Preterm and Early Term Infants**

In recent years, there has been an increasing recognition that infants from 34<sup>0</sup>/<sub>7</sub> to 36<sup>6</sup>/<sub>7</sub> weeks' gestation are physiologically immature and at higher risk for morbidity and mortality than term infants. Indeed, at a 2005 National Institutes of Health workshop, the decision was made to discourage calling such infants "near term" and instead label them "late preterm" to emphasize that these are premature infants at risk for a number of complications. From a liability standpoint, PCPs need to pay very close attention to

this group of infants both in the hospital and after discharge. Possible morbidities include, but are not limited to, respiratory distress, temperature instability, hypoglycemia, apnea, jaundice, and poor feeding. The rise in elective cesarean deliveries has resulted in increased numbers of infants born in the early term period of 37<sup>0</sup>/<sub>7</sub> to 38<sup>6</sup>/<sub>7</sub> weeks' gestation. Mortality and morbidity rates are higher among these infants as well.

There should be awareness of recommendations such as those promulgated by the AAP Committee on Fetus and Newborn. These recommendations are not meant to create a "standard of care" for liability purposes. Nevertheless, failure to follow them without justification may increase the chance of a malpractice lawsuit.

### **Procedures**

Primary care physicians are occasionally required to perform procedures on newborn patients. General rules for procedures involve competence, training, technique, consent, and documentation. In the non-emergency setting, the risks, benefits, and alternatives should be discussed with the parents, and this discussion should be documented. In the emergency setting, PCPs should use their best judgment. Will the newborn be harmed by delaying the procedure until consent can be obtained? If a newborn requires emergency intubation in the delivery room, then obtaining consent from the parents is unnecessary. This procedure generally falls under the *emergency exception to the informed consent doctrine*. Basically, informed consent is not necessary if the physician's intervention is needed on an emergency basis. For example, when called to a delivery that is complicated by meconium-stained amniotic fluid, the prudent pediatrician will explain to the parents that the neonate may be intubated. In many instances, time for such a discussion is not available. In this case, the pediatrician is well advised to put the interest of the baby at the forefront. Proceeding without consent is acceptable if the physician can clearly demonstrate the necessity of the procedure and the emergency nature of the situation.

Procedures should be accompanied by procedure notes. Box 85-5 contains the essential elements of the procedure note. The Joint Commission (see Tools for Practice) mandates a *time out* before any procedure to ensure patient safety. A time out is a planned period of discussion before the procedure is initiated, during which time the team verbally confirms the identification of the patient, the procedure to be undertaken, and the location. A time out can prevent a procedure from being performed on the wrong patient or on the wrong side. Even if the note is added to the chart later, the pediatrician should still document the indications, procedure performed, success or failure, complications, blood loss (if appropriate), and patient tolerance. If a follow-up study, such as a chest radiograph, is indicated, then the procedure note should include this information as well. Even noting that *chest radiograph is pending*

**BOX 85-5 Essential Elements of a Procedure Note**

- Date and time the procedure is performed and the documentation is completed
- Infant identification using 2 forms of identification
- Name of procedure
- Infant's diagnosis and the indication(s) for the procedure
- Consent (if none, then explain reasons for lack of consent)
- Performance of a *time out*
- Documentation of events, including sterile technique and preparation
- Blood loss, if applicable
- Complications (if none, then document)
- Infant's tolerance
- Results of indicated follow-up studies (eg, radiograph to confirm umbilical line position)

documents that the physician understands the importance of verifying the success or failure of the procedure.

**Umbilical Line Complications**

Some PCPs place umbilical lines as part of their routine practice in level II NICUs. Other PCPs will place umbilical lines on rare occasions and only under emergency situations. In either case, the attending physician needs to understand the potential complications from central venous and arterial access. The most common complications involve vasospasm, thromboembolic events, damage to the vessels being cannulated, exsanguination, and infection. Sterile technique should be used in the placement of central vascular access, and this precaution should be included in the pediatrician's procedure note. Line placement should be confirmed by radiograph, and documentation on all subsequent radiographs should note the line placement. Complications, if any, should be promptly evaluated. A referral to a neonatologist and vascular surgeon is likely appropriate for any infant with a complication related to vascular access.

**Transport and Referral**

If a neonate requires a higher level of care, then the pediatrician will generally arrange for a transfer of service or transport to another facility. The referring pediatrician will occasionally also be the admitting physician at the receiving facility. When is the referring pediatrician no longer responsible for the decision-making? Who is liable if the newborn suffers a complication after the receiving facility has been contacted? Who is liable if the newborn is harmed during transport? The answer is based, at least in part, on the role of the respective physicians. Is the referring physician making management decisions while the receiving physician is making

suggestions, or has the receiving physician taken over management of the patient?

In the case of *Sterling v Johns Hopkins*, a woman with severe preeclampsia died after transport, and the husband alleged that negligent telephone advice was given by the receiving facility. After reviewing the facts of this case, the court determined that the receiving physician was largely functioning in the role of a consultant and that the referring physician was responsible for the management decisions that were made.

**MEDICAL-LEGAL CONSIDERATIONS IN OFFICE CARE OF NEWBORNS**

Pediatricians spend up to 40% of their time providing preventive health care to children. During these health supervision visits, they are expected to provide an increasing number of services, from history taking and physical examination to immunizations to assessing developmental milestones to counseling, in a decreasing amount of time. Furthermore, during these visits, physicians need to diagnose medical problems that may not have been present or detectable in the first few days of life. For example, many ventricular septal defects are discovered only in patients older than 1 month, when pulmonary vascular resistance decreases. Failure to diagnose in a timely manner and failure to provide appropriate preventive care may give rise to liability.

Appropriate and timely follow-up of discharged newborns is essential to ensure safe and high-quality care. Several problems may not become apparent until after discharge but require intervention well before the traditional 1- to 2-week visit. This is especially true with late preterm infants, as discussed earlier in this chapter. Hyperbilirubinemia affects most healthy term newborns. Timely intervention is necessary to prevent severe and irreversible neurologic impairment. Primary care physicians who wish to minimize their liability while providing the best care are advised to follow the AAP Subcommittee on Hyperbilirubinemia clinical practice guideline published in July 2004 and updated in October 2009 (see Tools for Practice).

Newborn screening programs exist in every state, and testing is performed on more than 4 million newborns each year. With the introduction of tandem mass spectrometry, the capability now exists to screen for more than 50 disorders from a single blood spot. Presently, wide variability exists among states with regard to the number and type of disorders to be screened. Primary care physicians need to be aware of the specific screening tests mandated in their state. This awareness is particularly important for infants entering the pediatrician's practice who were born in a different state or outside of the United States. Comprehensive information can be found on the Web site of the National Newborn Screening and Genetics Resource Center ([genes-r-us.uthscsa.edu](http://genes-r-us.uthscsa.edu)). Furthermore, PCPs must be certain that organized systems are in place so that

results outside the reference range receive a timely response. Primary care physicians must also be certain that newborns who missed the newborn screen before nursery discharge, who had an inadequate or untestable specimen, or who had their screens obtained before 24 hours of consuming milk (breast milk or formula) receive the appropriate follow-up testing.

A comprehensive approach applies to newborn hearing screening as well. Given that permanent hearing loss is far more prevalent than most other conditions screened, early intervention is key to optimizing the child's functional and educational outcomes. In 2012, newborn screening for critical congenital heart disease (CCHD) was recommended by the US Health and Human Services Secretary's Advisory Committee on Heritable Disorders in Newborns and Children to promote early detection. Strategies have been published that recommend screening for low blood oxygen saturation through the use of pulse oximetry monitoring to detect CCHD in well-infant and intermediate care nurseries. Follow-up care processes must be incorporated into nursery screening programs to assure timely evaluation and intervention for infants who do not pass the screening protocol. Certain abnormalities, such as congenital adrenal hyperplasia, are considered emergencies and require immediate attention. Maintaining a high index of suspicion is key to making the diagnosis in a timely fashion.

Finally, PCPs must consider whether a diagnosis may affect future pregnancies for the parents or other family members. Primary care physicians should also refer the parents for appropriate genetic counseling when necessary. Appropriate preventive care covers a large number of issues that vary based on age. To ensure that necessary topics are covered during a visit, as well as to ensure that appropriate documentation is maintained, PCPs should consider using preprinted structured documentation forms. Physicians may choose to develop these forms themselves or use the forms that are available from the AAP.

## COMMUNICATION ISSUES

Communication is an integral component of providing excellent patient care. This concept is fundamental from a medical-legal standpoint as well as from an ethical perspective. The AAP and the American Board of Pediatrics recognize the importance of interpersonal and communication skills in providing quality patient care. Furthermore, a poor relationship between a patient and a physician is more likely to result in a lawsuit. (Information on communicating with families is contained in Chapter 49, Discussing Serious Symptoms, Results, and Diagnoses With the Patient and Family; and Chapter 9, Partnering With Families in Hospital and Community Settings.)

In addition to communication with the parents, physicians must make every attempt to ensure effective communication with other members of the health care team. Effective communication and care

transition are essential to safe and effective patient care. (See Chapter 7, Planned Coordinated Care to Support the Medical Home; and Chapter 51, Care of Children With Special Health Care Needs).

## PATIENT SAFETY

Errors in patient care are a major problem in health care. A seminal 1999 report of the Institute of Medicine, *To Err Is Human: Building a Safer Health System*, estimated that 98,000 deaths per year may be attributable to medical errors, and the Institute of Medicine demanded a complete shift in the health care culture. Although progress to date has been mixed, significant efforts have been made to improve patient safety. (See Chapter 5, Quality Improvement in Practice.)

When an error does occur, physicians are ethically and legally bound to disclose it to the patient or parent. Additionally, consoling and apologizing to the family can benefit both the patient and the physician and may help preserve the physician-patient relationship. Many states have adopted "apology laws," which prevent certain physician statements from being used at trial.

## MINIMIZING LIABILITY RISK

Approximately 1 in 7 physicians is sued every year. The current process of litigation is expensive, time consuming, and unpleasant. Even though no guarantees exist, methods can be used to minimize the chances of being named in a malpractice suit.

Maintaining competency is an essential task, not only for risk management, but also as an ethical imperative in its own right. Medicine today is a rapidly changing field. The AAP actively assists pediatricians with keeping current and developed a Web site that provides an individualized learning plan ([pedialink.aap.org](http://pedialink.aap.org)).

Pediatrics has become increasingly specialized, and most subspecialty and tertiary care services are organized into a regionalized system. These systems allow all PCPs to maintain professional ties with one another as well as with larger medical centers. This factor becomes important when appropriate consultation, referral, and transport may be necessary to provide optimal care.

A physician is occasionally faced with a particularly rare or challenging patient. In these situations, obtaining assistance is important. Maintaining contact with former attendees and mentors from residency can be helpful. Furthermore, academic centers with training programs will regularly discuss particularly difficult clinical cases during management conferences, morning report, grand rounds, and other meetings.

Keeping parents involved and informed is absolutely essential. Persons who feel uninformed and ignored can easily become frustrated and upset. Furthermore, they will quickly lose trust in the physicians and other clinicians. Mistrust, dissatisfaction,

and anger, combined with an undesirable outcome, can easily lead to a malpractice suit.

Proper documentation is an important component of risk management. One common mantra notes, “If it wasn’t documented, it wasn’t done.” Furthermore, poor documentation reflects poorly on the physician and can make even appropriate care seem to be shoddy and unorganized. Indeed, the PIAA found that of all the closed claims in 2004 involving a problem with the medical record, a payout occurred in 62%. The physician’s notes should be timed and dated, with *late entries* documented as such. All important events should be documented, along with the physician’s thought process and the rationale for the treatments.

Telephone advice can be a significant source of liability in pediatrics. Especially in the immediate newborn period, determining the clinical picture appropriately over the telephone may be especially difficult. When in doubt, the pediatrician should avoid diagnosing over the telephone. Furthermore, all telephone advice should be documented appropriately.

Finally, although large medical malpractice awards generate national headlines, medical practice is generally regulated by each state. State government legislation and case law cover a wide variety of issues that PCPs encounter, from the age of consent to resuscitation standards to professional licensing and discipline. Therefore, all practicing PCPs need to stay up to date on the laws and regulations that affect their practice. This task can be achieved by referring to the AAP Web site and to information disseminated by the physician’s local AAP chapter. The American Association of Family Physicians also provides its members with federal and state updates. In addition, state medical societies are a good source for current rules and regulations guiding practices. Box 85-6 summarizes strategies to minimize liability risk.

#### **BOX 85-6 Strategies to Minimize Liability Risk**

- Keep current through an individualized learning plan.
- Maintain professional ties with a referral medical center.
- Consult with a colleague when encountering a difficult situation; document these communications.
- Ensure that the consulting professional also provides documentation within the infant’s medical record (electronic or faxed consultation).
- Communicate frequently and honestly with parents.
- Document in a timely and thorough manner; include impressions, thought processes, and plan of care, including the plan for follow-up.
- Document telephone advice.
- If uncertainty exists, then do not diagnose over the telephone.
- Be aware of state laws that affect the practice.

## **CONCLUSIONS**

Physicians should make every attempt to understand their rights, duties, and liabilities. This chapter provides an overview of medical-legal considerations in the care of newborn infants.

Pediatricians and other child health care professionals are appropriately concerned about the liability risks they encounter when treating newborns. Nevertheless, many steps can be taken to minimize liability risk. Most of these steps, such as keeping current, documenting appropriately, and focusing on communication and safety, are also prerequisites for practicing good clinical medicine.

## Chapter 86

# PRENATAL PEDIATRIC VISIT

Deborah E. Campbell, MD

A prenatal pediatric visit during the third trimester of pregnancy is recommended for all expectant families as an important first step in establishing a child's medical home. The pediatric prenatal visit is often scheduled between 32 and 36 weeks' gestation. It provides an opportunity for the physician to gather basic information, provide information and advice to the family, identify high-risk situations, and promote parenting skills. A prenatal visit may be particularly valuable for first-time parents, families in which a long interval exists between births, families new to a practice, and families with high-risk pregnancies,

including pregnancy complications, multiple gestation, anticipated neonatal health problems, or a prior adverse pregnancy outcome. In a randomized controlled trial of prenatal pediatric visits among a group of low-income urban families, the prenatal visit was shown to affect important health outcomes, including the breast-feeding decision, satisfaction with the initial physician–parent relationship, and reduced emergency department use. The prenatal visit affords the prospective parents an opportunity to learn about the pediatric physician's office practice, the physician's approach to child health care, and the newborn's initial medical care during the early weeks after the delivery. Alternatively, parents may not have the opportunity to engage with the health professional in a full prenatal office visit, but they may initiate contact with their child's prospective physician by telephone, a brief office visit, or a group prenatal visit.

Group prenatal visits are an effective and efficient way to introduce prospective families to a practice and permit physicians to meet with prospective parents in a relaxed setting that fosters a free flow of information and discussion. If a group prenatal pediatric visit is the venue offered, then the physician should provide individual parents with an opportunity for a private conversation in order to gather individualized information. Many new parents do not meet their child's pediatrician before the baby's birth. No national data exist on the number of expectant families who complete a prenatal visit. A 2007 study conducted by the Institute for Vaccine Safety reported that 78% of the pediatric physicians surveyed offered a prenatal pediatric visit. Among the parents surveyed, 39% of first-time mothers completed a prenatal pediatric visit. Previous studies have reported that 70% to 90% of pediatricians and family physicians offer prenatal pediatric visits, with wide variation (22%–65%) in the reported rates of mothers completing a prenatal pediatric visit. Among urban poor women, rates as low as 5% have been noted for prenatal pediatric visits.

The National Center for Health Statistics reports that less than 75% of pregnant women in the United States begin prenatal care in the first trimester. However, 93% of women will be in care by the second trimester with only 7% of pregnant women receiving late or no prenatal care. Racial and ethnic disparities in the initiation and rates of utilization of prenatal care persist. Black and Hispanic women remain less likely to enter care in the first trimester or to have adequate prenatal care (complete greater than 80% of prenatal care visits for gestational age). Two-thirds of pregnant women attend a childbirth class. Late entry into prenatal care (after the first trimester) increases the risk that a child will not receive all the recommended immunizations and routine well-child care.

The prenatal pediatric visit has 5 goals: to ascertain pertinent aspects of the prenatal history, to review the family history and identify disease risks for future health problems and genetic or chromosomal disorders that may affect the infant, to identify psychosocial factors that may affect family functioning and the family's adjustment to the newborn, to introduce anticipatory guidance about early infant care and infant safety practices, and to provide a foundation on which to build a

family health professional partnership. Box 86-1 lists goals and topics for discussion. Breastfeeding promotion is another key component of this visit, particularly for expectant mothers who have not yet decided on a feeding method or are unsure about the benefits of breastfeeding or their ability to successfully breastfeed their infant. Breastfeeding education provided in the prenatal setting is a proven strategy that increases the initiation of breastfeeding. Figure 86-1 provides a sample format for discussing and documenting elements of the prenatal pediatric visit.

From a financial and practice management standpoint, debate exists within the medical community regarding whether a fee should be charged for the prenatal pediatric visit. Some advocates argue that the prenatal visit is an important marketing tool to building a physician's practice; opponents counter that the professional's time and expertise are valuable and that a charge should be levied for the visit. Individual professionals and practices will need to make their own decisions regarding benefits derived from this visit and whether payment is

appropriate. Many insurance carriers do include a prenatal pediatric visit as a covered benefit for first-time parents, for high-risk pregnancies, and if the family requests a conference.

- *You and Your Pediatrician* (handout), American Academy of Pediatrics (shop.aap.org)
- *Where We Stand: Newborn Discharge From Hospital* (Web page), American Academy of Pediatrics ([www.healthychildren.org/English/ages-stages/prenatal/delivery-beyond/Pages/Where-We-Stand-Newborn-Discharge-from-Hospital.aspx](http://www.healthychildren.org/English/ages-stages/prenatal/delivery-beyond/Pages/Where-We-Stand-Newborn-Discharge-from-Hospital.aspx))

### BOX 86-1 Visit Goals and Topics to Discuss at the Prenatal Visit

1. Establish parent–physician relationship
  - a. Parent perspectives on what qualities they are hoping to find in their child's health professional and their expectations of the practice and pediatric physician
  - b. Specific parent concerns or questions
  - c. Health professional reflects on own perspectives about pediatric primary care and expectations about the parents' role in their child's care
2. Obtain family and prenatal history
  - a. Parents' ages and occupations, health insurance coverage for parents, and proposed health insurance coverage for the infant
  - b. Specifics of family relationships, cultural beliefs, and parenting beliefs and experiences
  - c. Perceived impact of impending birth on the family and family functioning—family's preparation for the infant (adequacy of resources)
  - d. Family social habits and potential environmental/occupational exposures, including tobacco, alcohol, lead, and drug use
  - e. Family medical and pregnancy history—known hereditary or genetic conditions
3. Provide information and support
  - a. Identify high-risk situations
    - i. Prenatal evaluations, prenatal diagnoses, family genetic history maternal medical conditions that may affect the timing and mode of delivery or the newborn
    - ii. Multiple gestation
    - iii. Previous adverse pregnancy outcome
    - iv. Mental health, illicit drug, prescription, and/or over-the-counter medication use, tobacco use, and domestic violence issues
  - b. Delivery plans
    - i. Parent concerns: *birth plan*
    - ii. Hospital where delivery will occur: whether the practice provides the baby's care or if other physicians will be responsible
      - (1) Rooming-in
      - (2) What will happen if the infant requires specialized or neonatal intensive care
    - iii. Home birth
  - c. Initial newborn care after the birth
    - i. Normal newborn transition including state regulation
    - ii. Initial assessment, including postnatal evaluations of any prenatal test results of concern
    - iii. Preventive care, including immunizations, newborn screening (blood spot, hearing, jaundice, critical congenital heart disease)
  - d. Infant feeding choices, benefits of exclusive breastfeeding, early skin-to-skin care, and initiation of breastfeeding within the first hour after birth
  - e. Circumcision decision
  - f. Anticipated timing of the baby's discharge from the nursery or birthing center; factors that determine when the baby can go home
4. Build parenting skills; anticipatory assessment and guidance about potential for postpartum depression
5. Provide safety and anticipatory guidance including car seat use, avoidance of second-hand smoke exposure, safe sleep practices, sibling responses
6. Schedule visits: hospital care after the delivery, during the first week of life (first postdischarge follow-up visit by 3–5 days of age) and subsequent well-child care visits
7. Discuss how and when the parents should contact the child's pediatric care professional and specific practice routines

**Chapter 87****CARE OF THE NEWBORN  
AFTER DELIVERY**

*Diane E. Bloomfield, MD; Elaine A. Dinolfo, MD, MS;  
Faye Kokotos, MD*

Parental concerns after the birth of their infant frequently focus on the health and *normality* of their newborn. These concerns may be heightened by a suspected fetal abnormality diagnosed prenatally, a prior adverse pregnancy outcome, or an unfavorable maternal medical condition. The mother's own health and her experiences during the labor and delivery process also affect her response to her newborn and receptivity to information about the baby. Answering questions and addressing parental concerns will reassure parents and lessen anxiety. Knowing that the physician will be available to them, both in the nursery and after the family leaves the hospital, enhances parental satisfaction.

**NEWBORNS WITH SPECIAL HEALTH  
CARE NEEDS**

Parents of babies who are born preterm or at low birth weight or who are found to have a congenital malformation or other condition that requires specialized medical care experience additional stress and anxiety. The families of otherwise healthy term and late preterm babies who develop an illness in the immediate newborn period (eg, transient tachypnea of the newborn, hypoglycemia, infection, hyperbilirubinemia) may exhibit emotional and psychological distress equal to or exceeding that expected from parents of the most seriously ill neonates. Caring for the parents is therefore as important as caring for the newborn, especially if parents are young or have personal health problems, an inadequate personal support network, or apparent limited coping skills.

Helping parents express an understanding of their child's health needs and the effect the illness has on their family is ideal. Addressing any stated (or implied) assertions of guilt by or toward the mother as being responsible for the baby's health issues is particularly important. Searching for a reason why the newborn became sick after birth is common for mothers and families. In some cultures, illness is viewed as punishment for some wrong committed by the mother or another family member. Some parents need to be given permission to ask questions, express fears, and discuss concerns regarding their hopes and dreams for their child and family and whether these hopes and dreams can remain the same or must change. Depending on the circumstances surrounding the birth and the health concerns for the mother and baby, families can be expected to express a wide range of feelings and emotions, including grief, anger, and fear. Typically these concerns must be addressed before the parents and family can engage in significant discussions about the baby and the proposed evaluation and treatment options.

**INITIAL CARE OF THE NEWBORN****Care of the Healthy Newborn After Delivery**

In addition to the initial assessment and any resuscitation or stabilization performed in the delivery room, the early components of newborn care are oriented toward preventing common conditions that can cause early, serious harm to the neonate. Anticipatory care includes preventing hypothermia, recognizing neonates at risk for hypoglycemia or infection, and administering topical eye care and parenteral vitamin K. Discussion of the initial assessment and care of the sick newborn are provided in Chapter 109, Assessment and Stabilization at Delivery; and Chapter 110, Identifying the Newborn Who Requires Specialized Care.

Babies who transition normally can be transported to the nursery after a period of bonding with their parents that includes early skin-to-skin care and the opportunity to breastfeed within the first hour in the delivery room. Infants may also remain with the mother for the entire length of the hospital stay in centers where all care is provided in the mother's multipurpose labor–delivery–recovery–postpartum room. Irrespective of hospital maternity and newborn unit structure, mothers should be encouraged to room-in with their newborns to promote frequent breastfeeding and support early caregiving activities, including adaptation to parenthood by the new parents.

**Breastfeeding**

Initial postnatal care of the neonate should include the opportunity for breastfeeding soon after delivery. Early initiation of breastfeeding, breastfeeding on demand, and rooming-in have been shown in meta-analyses to have a positive effect on mother–infant bonding and breastfeeding in primiparous women, reducing the occurrence of maternal complications, formula use, and early breastfeeding discontinuation. If feasible, breastfeeding should be initiated within 1 to 2 hours after delivery, optimally within the first hour.

A recent caution has been raised regarding the need for observation of the primiparous woman who is breastfeeding for the first time immediately after delivery. Reports from Israel and France describe several infants who experienced cardiopulmonary compromise while breastfeeding, positioned prone on the mother's abdomen. Supporting and sustaining early breastfeeding efforts includes education regarding the newborn's early feeding skills, positioning, latch-on and suckling, and the frequency of demand feeding in the early postnatal period. Mother–baby pairs should be evaluated during the hospital stay to assess the mother's knowledge about breastfeeding and the adequacy of the breastfeeding process and to identify information and resources needed to support breastfeeding after hospital discharge. A particular challenge is encountered when women express the intent to both breastfeed and bottle (formula) feed and desire to implement this practice while in the hospital.

Mothers receiving epidural anesthesia for postoperative pain control do not experience negative effects on breastfeeding if bupivacaine is used or if they are receiving oral ibuprofen. Buprenorphine use has been

shown to affect early breastfeeding. (See Chapter 88, Breastfeeding the Newborn, for more information on initiating breastfeeding.)

### Eye Care

Prevention of ophthalmia neonatorum by providing topical prophylaxis after birth is an effective prevention strategy. Ophthalmia neonatorum is inflammation of the conjunctivae in the first month of life. Ophthalmia neonatorum is classified as 1 of 4 forms: chemical conjunctivitis, bacterial conjunctivitis, chlamydial conjunctivitis, or viral conjunctivitis. The most severe cases of ophthalmic neonatorum are caused by *Neisseria gonorrhea* and *Chlamydia trachomatis* infections. *C. trachomatis* is the most commonly reported sexually transmitted infection in the United States. Fifty percent of infants delivered vaginally will acquire infection. Of those infants who are infected at delivery, 25% to 50% will develop conjunctivitis and 5% to 20% will suffer from pneumonia. Other bacteria also cause conjunctivitis in neonates, including *Haemophilus influenzae*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Enterococcus*, and other gram-negative organisms. Contamination with these organisms may occur through horizontal transmission routes postnatally and through contact with nursery and hospital staff, parents, and other caregivers. Gonococcal conjunctivitis will typically develop within 48 hours of birth, in contrast to chlamydial conjunctivitis and herpetic conjunctivitis, which more commonly occur at 4 to 7 days and 1 to 2 weeks of age, respectively.

Credé, in 1881, recognized that application of silver nitrate to newborn conjunctivae greatly reduced the incidence of gonococcal ophthalmia neonatorum. The epidemiology of ophthalmia neonatorum changed over the last century, reflecting the increase in *C. trachomatis* infection worldwide. However, the routine installation of antibiotic eye drops combined with improved prenatal care and preventive treatment resulted in a significant decrease in neonatal conjunctivitis, from 10% to 0.3%.

With appropriate prenatal care that includes cervical cultures, the need for routine eye prophylaxis in light of the risk for chemical conjunctivitis as a complication of prophylaxis may be questioned. Bell et al, in a randomized, double-blind study of low-risk infants (those whose mothers were screened for cervical infection with gonococcus and *Chlamydia*) demonstrated that 1% silver nitrate or 0.5% erythromycin ophthalmic ointment decreased the incidence of conjunctivitis (infectious or noninfectious) compared with no prophylaxis. Of the 630 infants randomized to 3 groups, 17% developed conjunctivitis, with 63% of cases in the first 2 weeks. The rates of conjunctivitis were 15% in the no-treatment group, 9% in the erythromycin group, and 8% in the group treated with silver nitrate. The authors concluded that silver nitrate had no harmful effects and may provide some benefit, although the effect on organisms of low virulence was not robust. Most states require routine eye prophylaxis of all newborns, but the data suggest that elective treatment based on maternal prenatal surveillance for infection may be a reasonable alternative. The

American Academy of Pediatrics (AAP) currently recommends universal prophylaxis of all newborns with 1% silver nitrate, 0.5% erythromycin, or 1% tetracycline. A 2.5% povidone-iodine ophthalmic solution is also effective in preventing ophthalmia neonatorum. Chemical conjunctivitis can develop during the first 24 hours of life in response to topical eye prophylaxis with silver nitrate, but the incidence has declined to approximately 1% since the concentration of the silver nitrate solution was reduced to 1%.

### Vitamin K Prophylaxis

Unexpected bleeding in a healthy newborn may be caused by vitamin K deficiency. Prophylactic administration of vitamin K reduces the incidence of bleeding. Parenteral administration of vitamin K has been the standard of care since the 1961 AAP recommendation. Concern about the possible relationship between parenteral vitamin K and childhood cancer led to debate regarding parenteral administration, but more recent research failed to support these earlier claims. The AAP Committee on Fetus and Newborn continues to recommend that all newborns receive vitamin K prophylaxis via the parenteral route.

Vitamin K is an essential component in the synthesis of 4 coagulant proteins—factors II, VII, IX, and X—and neither vitamin K nor these factors cross the placenta efficiently. At birth the fetal levels of these clotting factors and levels of protein C and protein S are approximately 50% of adult levels. This circumstance, combined with a sterile gut and low levels of vitamin K in human milk, increases the risk for hemorrhage in the newborn.

Hemorrhagic disease of the newborn, also referred to as vitamin K deficiency bleeding (VKDB) occurs in 3 forms: early (first 24 hours), classic (days 2–7 of life), and late (after 1 week of age). Bleeding in the first hours of life is frequently associated with maternal use of drugs such as anticoagulants, barbiturates, carbamazepine, phenytoin, and some cephalosporins, as well as tuberculostatic agents such as rifampicin and isoniazid. Risks to the neonate at this time are intracranial hemorrhage and gastrointestinal bleeding.

During the first week newborns with the classic form of VKDB may develop prolonged bleeding during and after circumcision, cord separation, or phlebotomy. The incidence of classic VKDB is approximately 0.25% to 1.7%, whereas late VKDB, occurring from week 2 through 12, has an incidence of 4.4 to 7.2 per 100,000 live births. Late-onset VKDB occurs primarily among exclusively breastfed infants who have not received adequate vitamin K and in infants who have underlying diseases such as biliary atresia, cholestatic jaundice, or malabsorption syndromes. Late-onset VKDB can cause cerebral hemorrhage with devastating sequelae.

Inception of vitamin K prophylaxis worldwide has greatly reduced the incidence of classic VKDB. Controversy regarding the route of administration has led to development of alternative regimens. The disadvantages of intramuscular vitamin K include local trauma, increased cost, and concern about increased levels of the vitamin potentiating the risk of childhood cancer. Oral preparations are less costly but may be

difficult to administer properly. When a single dose of oral vitamin K is given, the incidence of classic VKDB is nil, with a concomitant reduction in late VKDB from 4.4 to 7.2 per 100,000 live births to an incidence of 1.4 to 6.4 per 100,000. However, parenteral vitamin K prophylaxis prevents both classic and late VKDB, except for those newborns with rare severe malabsorption syndromes.

In 1990, 2 studies reported from Bristol, England, suggested an association between parenteral vitamin K administration and childhood cancer. Golding et al proposed as much as a 2-fold increase in childhood cancer. Subsequent research performed by others has failed to confirm the association. The AAP Vitamin K Ad Hoc Task Force reviewed the Golding study, as well as other contrary research, and concluded that a link between vitamin K administration and childhood cancer was not established. Current recommendations remain unchanged—all newborns receive intramuscular vitamin K at a dose of 0.5 to 1.0 mg. Continued research into the efficacy, safety, and bioavailability of oral preparations and optimal dosing regimens to prevent late VKDB remains an important need.

### PHYSICAL EXAMINATION: HOW MANY EXAMINATIONS ARE NEEDED?

The purposes of the newborn examination are to assess the transition from fetal life to the extrauterine environment, to provide reassurance to parents that their newborn is healthy, and to detect potentially serious conditions in healthy-appearing neonates before discharge from the hospital. However, not all conditions that affect the newborn will be detected in the immediate postnatal period. Routine neonatal examination fails to detect the presence of heart disease in 50% of babies born with a congenital heart defect. In addition, only one-third of infants with congenital cataracts are diagnosed during the course of their newborn nursery stay. This low rate of diagnosis has led some physicians to question the number of assessments that need to be performed before the newborn's nursery discharge and the role of screening tests to assist in early diagnosis of potentially serious health conditions. An evidence review conducted in 1999 found few studies evaluating the efficacy of 1 versus 2 neonatal examinations in detecting congenital anomalies in low-risk, healthy newborns before hospital discharge. One controlled trial did determine that more abnormalities were identified before hospital discharge if 2 examinations were conducted; however, in the group of newborns studied, no difference was noted in specific clinical outcomes evaluated.

Current practice in most US hospitals providing newborn care is for the neonate to undergo at least 2 examinations before nursery discharge. However, the healthy term newborn delivered and discharged home within 24 hours may undergo only a single examination. Neonates whose delivery is attended by a physician will typically have a brief assessment performed in the delivery room and a more comprehensive examination after admission to the newborn nursery. Most births, however, are not attended by a pediatrician.

Therefore most newborns will be examined by a physician within the first 24 hours, with a second examination occurring in preparation for the hospital discharge. Whenever possible, the physician should perform these assessments in the mother's room to facilitate history taking, to provide an opportunity to evaluate parent-infant interactions, and to promote parent involvement. It also affords the physician the opportunity to demonstrate the newborn's abilities, answer parent questions, discuss any variations or abnormalities detected on examination, and provide anticipatory guidance and breastfeeding support.

Discussion about newborn care issues and continuity of care has been shown to enhance maternal satisfaction with early newborn care. Hospitals with rooming-in policies that support complete care delivery in the mother's room facilitate this process. Studies have shown that half of the missed abnormalities were congenital dislocation of the hip. Irrespective of whether the infant is examined once or twice before nursery discharge, a follow-up assessment at 3 to 5 days of age is paramount to ensure that conditions exhibited later during the first week of life are detected so that appropriate interventions can be initiated.

### Glucose Screening

No evidence has been found to justify routine measurement of glucose in appropriately grown, healthy, term neonates. (See Chapter 105, Transient Metabolic Disturbances in the Newborn.) A normal blood glucose level in a neonate during the first days of life may vary from 27 to 108 mg/dL (1.5–6 mmol/L), and approximately 10% of healthy newborns will have a blood glucose level less than 47 mg/dL (2.5 mmol/L) during the first 72 hours of life. Mean blood glucose levels for breastfed infants are slightly lower at 65 mg/dL (3.6 mmol/L) than formula-fed infants at 72 mg/dL (4 mmol/L). In a recent clinical report the AAP Committee on Fetus and Newborn (COFN) noted that current evidence does not support a specific concentration of glucose that can discriminate normal from abnormal or can potentially result in acute or chronic irreversible neurologic damage. However, early identification of at-risk infants (late preterm and term small for gestational age infants and infants of diabetic mothers/large for gestational age infants) with institution of prophylactic measures to prevent neonatal hypoglycemia is recommended. The report provides strategies for screening and management of at-risk neonates within the first 4 hours following birth and for infants between 4 and 24 hours of age. Within the first hour of life asymptomatic, at-risk neonates should breastfeed or formula feed and have their initial glucose screen performed 30 minutes after the feeding. If the initial glucose screen is less than 25 mg/dL (1.4 mmol/L), the asymptomatic, at-risk infant should be fed again and the glucose repeated 1 hour after the second feeding. Management approaches are guided by the presence of clinical symptomatology, specific risks, and glucose levels.

Some nurseries may perform an initial glucose screen on all newborns. Cornblath recommended using an operational threshold of 36 mg/dL (2.0 mmol/L)

for intervention in infants at risk for hypoglycemia, with the goal of raising the blood glucose level above 47 mg/dL (2.6 mmol/L). AAP COFN currently recommends a glucose threshold of 35 to 45 mg/dL (1.94–2.5 mmol/L) in asymptomatic, at-risk infants between 4 and 24 hours of age. The frequency and duration of glucose monitoring for newborns at risk for hypoglycemia typically extends for a period of 12 to 24 hours based on the specific risk factor and the infant's response to feeding. Individual hospital protocols delineate these processes and criteria for transfer of infants to a special or neonatal intensive care unit for intravenous therapy.

### Screening for Congenital Heart Defects

Screening during both the prenatal and the postnatal period to diagnose a variety of conditions with potential short- or long-term consequences for the newborn is increasing in frequency as technology advances and parent advocacy grows. Early identification of potentially life-threatening cardiac defects before the infant develops symptoms is the rationale for implementation of screening for critical congenital heart defects (CCHD). Current guidance supports the examination of a newborn's cardiovascular system with both prenatal ultrasound and physical examination at birth, recognizing that neither screening assessment will identify all newborns with CCHD. For example, predictive value of a heart murmur during the first days of life is reported as 54%. The Secretary of Health and Human Services, with the endorsement of the AAP, now recommends that screening for CCHD with pulse oximetry be included in the uniform newborn screening panel.

Pulse oximetry is recommended as a screening test for the early detection of CCHD based on this assumption that life-threatening heart diseases in newborns may not be detected by physical examination and that many hypoxic heart defects do not have an audible murmur during the early neonatal period. In the US congenital heart defects occur in 9 per 1,000 live births, with approximately 4,800 infants born annually with 1 of the 7 CCHD defects. Development of hemodynamic instability secondary to CCHD leads to multiple organ system compromise, most notably hypoxic-ischemic brain injury. Periventricular leukomalacia has been detected by MRI in up to 39% of neonates with CCHD prior to surgery.

A collaboration of the AAP and the American Heart Association studied the available research addressing the usefulness of pulse oximetry for the detection of CCHD. Techniques and results varied among studies, with some studies demonstrating reasonable rates of detection. Of the infants identified with suspected heart disease, 94% had a structural cardiac lesion (97% specificity), but only 11.4% of these infants had a potentially life-threatening cardiac lesion. Ideally, the rate of false positive results should be minimal to reduce unnecessary echocardiography.

In September of 2011 the HHS Secretary's Advisory Committee on Heritable Disorders in Newborns and Children convened a working group to evaluate and offer strategies for universal newborn screening for CCHD. This group focused on seven specific structural

heart lesions associated with hypoxia: hypoplastic left heart syndrome; pulmonary atresia; total anomalous pulmonary venous return; transposition of the great arteries; tricuspid atresia and truncus arteriosus.

The HHS group published strategies to implement a universal program that includes equipment, training, personnel and specific recommendations using pulse oximetry. This publication provides detailed information and an important screening algorithm for use in nurseries. Sentinel implementation recommendations include targeting healthy newborns, using motion-tolerant pulse oximeters and screening after 24 hours of life. Oxygen saturations should be obtained in both the RIGHT hand and either foot to capture postductal oxygenation. A passing screen should include oxygen saturation of  $\geq 95\%$  in either extremity with  $\leq 3\%$  absolute difference between the upper and lower measurements. If an initial screen finds hypoxia it should be repeated to reduce false positives. Importantly, a saturation of less than 90% requires immediate evaluation. A true positive screen necessitates the exclusion of pulmonary and or infectious causes of hypoxia and diagnostic echocardiogram.

Despite the recommendation of the Secretary of HHS individual states will determine how they will implement pulse oximetry into newborn screening programs. The AAP strongly recommends and supports national screening and surveillance of CCHD to reduce the morbidity and mortality associated with delayed diagnosis.

### Newborn Blood Spot Screening

Newborn blood screening (NBS) is performed on 4 million infants each year in the United States, representing the largest application of genetic testing in medicine. NBS is an essential preventive public-health program to identify disorders that may affect long-term health. Early detection and treatment of a variety of metabolic, genetic, and infectious diseases may lead to a significant reduction in death, disease, and associated disabilities.

NBS began with the pioneering work of Dr Robert Guthrie, who developed a screening test for phenylketonuria by using a drop of blood placed on filter paper. In the succeeding 40 years the technology and scope of screening has led to the ability to test metabolic, infectious, and genetic conditions. In 1990, tandem mass spectrometry (MS-MS) was introduced as a more accurate and expansive mode of testing. MS-MS allows for the detection of more than 30 analyte errors. MS-MS combined with radioimmunoassay, fluoroimmunoassay, enzyme-linked immunosorbent assay, and DNA analysis has greatly expanded NBS potential. Each state public health system has a program to screen, identify, and treat its newborn population. The programs require the involvement of primary-care pediatricians as well as subspecialists. The primary-care physician must be aware of the tests performed, the protocols to repeat testing, and the referral base for infants with positive tests. Great interstate variability exists in the communication systems established between the family of the newborn, the primary-care physician, and the NBS program. Interstate variation also exists in parental education,

NBS consent, and diseases screened and tracking of results. Information is available at state public-health Internet sites, the Health Resources and Services Administration, and the National Newborn Screening and Genetics Resource Center.

However, universal standards exist regarding collection and storage of specimens. Only persons who are properly trained should collect specimens. Blood should be drawn from the newborn via heel stick using the medial or lateral aspect of the lower foot with saturation of the filter paper spots. Capillary tube or venipuncture is also adequate, but central lines or umbilical lines should be avoided to prevent false results. The filter paper must be handled carefully because alcohol, iodine, skin oil, petroleum jelly, urine, or feces may contaminate the specimen. Specimens should be collected before nursery discharge and before 72 hours of age.

NBS samples obtained before 24 hours of life can create false-positive results, although the use of MS-MS may eliminate this problem. If a specimen is collected before 24 hours, then a second specimen should be obtained by 7 days. If a neonate is to receive a blood transfusion, then the NBS sample must be drawn before blood is given and repeated 2 months later. Premature and low-birth-weight newborns may have false-positive results on several of the routine NBS tests, such as those for thyroid function, congenital adrenal hyperplasia, tyrosinemia, and galactosemia. Experts recommend that preterm, low-birth-weight, and very sick neonates be retested later, at 2 weeks of age or before discharge from a neonatal intensive care unit. Filter-paper specimens should dry for at least 3 hours in room air before placement in transport envelopes. The samples should be kept from heat and humidity, given that these environmental conditions may denature enzymes to create false results. All specimens are sent to regional, centralized laboratories where strict standards and controls must be maintained. The hospital of origin and, ideally, the medical home of the infant must be identified so that re-evaluation and intervention for a positive test may happen rapidly and efficiently.

The AAP Task Force on Newborn Screening has made a series of recommendations summarized in the 2000 report *Serving the Family From Birth to the Medical Home*. The Task Force emphasized that NBS is not merely a testing program but rather a tracking, diagnostic, therapeutic, and evaluation program. As technology continues to develop, the ability to recognize more potential diseases will be available through both government-sponsored programs and private industry. However, the ability to treat or alter disease may lag behind. The Task Force's key recommendations include (1) developing adequate public health infrastructure to support advanced testing, tracking, informing and treating disease, (2) advancing the involvement of health professionals, families, and the public in development and oversight of NBS, and (3) charging public health agencies with ensuring adequate infrastructure, financing, and policies for adequate surveillance and research related to newborn screening.

With the extensive availability of MS-MS, almost all states have expanded screening programs to

encompass more disorders. In 2005 the AAP endorsed the report of the American College of Medical Genetics (ACMG) recommending that each state screen newborns for a core panel of 29 treatable diseases and an additional 25 conditions that may be detected with the new technologies. The Federal Advisory Committee on heritable Disorders in Newborns and Children also endorsed the ACMG recommendation. In 2008, 21 states and the District of Columbia fully implemented the ACMG panel. There remains interstate variability in newborn screening panels although the potential for a national policy remains in the future. Because of the rapid expansion in technology primary care pediatricians may soon be required to follow and treat diseases for which there is little familiarity. The ACMG supported by the Maternal and Child Health Bureau of Health and Human Services has developed web supported ACT sheets to assist physicians in the immediate response to out of range newborn screen results. These informational sheets are designed to supplement state sponsored information and follow-up. Physicians, in union with state agencies, must develop office policies for recognition, referral, and follow-up of those children identified by newborn screening. There must also be alliance between local, state and national entities to maximize the positive effects on children and families that this program is intended to provide.

### Prevention of Perinatal HIV Transmission

Perinatal HIV transmission remains the primary source of pediatric HIV/AIDS in the United States. The risk of infection for a neonate born to an HIV-positive mother has been reduced from 25% to less than 2% by the use of currently recommended prenatal antiretroviral therapy and obstetric interventions for women who are aware of HIV infection early in pregnancy. The Institute of Medicine and the Centers for Disease Control and Prevention recommend that all pregnant women receive counseling regarding HIV infection and perinatal HIV transmission and its prevention and that HIV testing be performed on entry into prenatal care and again in the third trimester. For women who have not been tested prenatally, rapid HIV testing in the labor and delivery unit can reduce the risk for mother-to-child transmission. HIV prophylaxis, even when begun during labor and delivery, has been shown to reduce mother-to-child HIV transmission by as much as 50%. Two states, New York and Connecticut, perform HIV screening on the newborn blood spot sample.

### Infants at Risk for Sepsis

The approach to the infant at risk for infection is discussed in detail in Chapter 102, The Newborn at Risk for Infection. New guidelines for the evaluation of infants exposed to intrapartum Group B *Streptococcus* were accepted by the AAP in December, 2010.

### Screening for Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH), if untreated, can lead to the development of osteoarthritis, chronic pain, and activity limitations. Although screening for

DDH has been considered a standard of care for over 4 decades, conflicting recommendations remain regarding the evidence that supports the efficacy of screening for DDH and the appropriate screening strategy and treatment options to improve functional outcomes. DDH represents a spectrum of anatomic abnormalities that involve improper alignment or abnormal growth of the femoral head and acetabulum. Reported rates of DDH vary between 1.5 and 20 per 1,000 live births, with 1% to 10% of affected infants having an identifiable risk factor. A recent review of the available evidence by the United States Preventive Services Task Force assessed the efficacy of early detection methods and intervention outcomes.

Breech presentation, family history of DDH, and female gender have been found in fair-quality, case-controlled and observational studies to be most consistently associated with DDH. Among affected infants, only 10% to 27% of patients diagnosed with DDH have been reported to have a risk factor other than female gender. Notably, 60% to 80% of hips assessed as abnormal on the initial newborn examinations are normal on follow-up examinations between 2 and 8 weeks later. Even among neonates with evidence of mild dysplasia on ultrasonography of the hip, clinical resolution occurs between 6 weeks and 6 months of age. Studies have evaluated the efficacy of universal ultrasound screening of newborns for DDH and have found that the evidence to support this recommendation is insufficient. Neither the AAP nor the Canadian Paediatric Society (CPS) recommends routine ultrasonography.

A recent retrospective, observational study reinforces the value of a positive Ortolani sign in a neonate as signifying that the femoral head is not properly within the acetabulum, warranting further evaluation. Current recommendations from the AAP and the CPS are for serial clinical examination of an infant's hips at all periodic health examinations until 12 months of age and a closely monitored period of observation for newborn infants with clinically detected DDH. Positive Ortolani and Barlow tests are indicators for close surveillance by the pediatric physician, with repeat evaluation by 3 weeks of age to document either resolution or persistence of clinical findings. In those infants with spontaneous resolution, imaging, either ultrasonography at 6 weeks of age or x-ray at 4 months of age, should be performed. If the positive findings persist at the 3-weeks visit, then the newborn should be referred to an orthopedist for management. Age-appropriate imaging is also recommended by the AAP for female newborns born breech or with positive family history of DDH. In contrast, the CPS does not recommend imaging for high-risk infants. Because of the biologic nature of DDH, not all dislocatable hips will be detected at birth. If during periodic visits suspicions are raised by the examination or because of parental concern, confirmation by referral to an orthopedist or by imaging is recommended by the AAP.

### Hearing Screening

Over 90% of newborn infants have their hearing screened before nursery discharge. The Joint Committee on Infant Hearing in its 2007 position paper

created guidelines for early hearing detection and intervention programs. A detailed discussion about infant hearing screening is available in Chapter 26, Auditory Screening.

### Umbilical Cord Care

The umbilicus is rapidly colonized after birth. Up to 90% of newborns whose umbilicus is not treated with umbilical antiseptics show evidence of colonization with *S aureus* at the time of nursery discharge. Although infants with heavy bacterial colonization are at higher risk for developing infection, the overall risk of serious infection is less than 1%. Wide variation exists in hospital practices regarding the use of antiseptics in infant cord care. The most commonly used antiseptics are chlorhexidine, triple dye, hexachlorophene, and 70% alcohol. Dry cord care is associated with higher rates of colonization with *S aureus*, whereas chlorhexidine use has been shown to decrease colonization by 33%. Cord separation typically begins by 4 to 6 days of age, with complete separation by 2 weeks of age. Separation takes longer in preterm infants than in term infants. Delayed separation beyond 3 weeks of age should alert the clinician to a possible immunologic defect or anatomic abnormality, such as a patent urachus. Time to cord separation has also been shown to increase with the use of chlorhexidine, alcohol, and repeated applications of triple dye.

Antiseptic agents on the umbilical cord prevent bacterial colonization and possibly infection. However, recent changes in maternity care practice have resulted in reduced bacterial cross-contamination of infants and have made infections a rare event to the extent that many hospitals have adopted dry cord care. A recent Cochrane review concluded that evidence is insufficient to know whether antiseptics have any additional advantage over keeping the cord clean and dry.

### Hepatitis B Virus Vaccine

The acute and chronic consequences of hepatitis B virus (HBV) infection are major health problems. Acute HBV infection can cause liver failure, leading to death, whereas chronic HBV infection can cause long-term liver damage such as cirrhosis and hepatocellular carcinoma. Approximately 12.5 million persons have been infected with HBV during their lifetime, an estimated 1.25 million Americans have chronic, life-long HBV, and 4,000 to 5,000 deaths occur each year in the United States from HBV-related chronic liver disease, such as cirrhosis and liver cancer.

The risk of chronic infection increases with decreasing age; people who are infected in early childhood experience a disproportionately large burden of disease attributable to HBV infection. As many as 90% of newborns exposed to HBV from their mothers at birth become carriers, 30% to 50% children exposed between 1 to 5 years become carriers, and by adulthood the risk of becoming a carrier is 6% to 10%. Immunization with HBV vaccine is the most effective measure for preventing HBV infection and its consequences. Universal vaccination can control vertical and horizontal transmission of HBV and the sequelae of chronic HBV infection. In populations in which the

infection is highly endemic, routine childhood immunization has led to decreases in the prevalence of chronic infection, as well as declines in childhood mortality from hepatocellular carcinoma. In countries with low prevalence rates the benefits of universal neonatal vaccination will not be apparent until 2 to 3 decades later because infection in these countries occur among adolescents and young adults through percutaneous or sexual routes. The Advisory Committee on Immunization Practices expanded its HBV immunization recommendations in 1991 to include all newborns primarily to stop HBV transmission among children and eventually to prevent HBV infections in adolescents and adults. The currently available HBV vaccines are safe and have an efficacy of above 90%. The vaccines are produced by recombinant DNA technology and have been licensed in the United States in single-antigen formulations and as components of combination vaccines. Long-term studies of adults and children indicate that immune memory remains intact for 15 years or more and protects against clinical acute infections and chronic HBV infection, even though anti-hepatitis B surface antigen (HBsAg) concentrations may become low or undetectable over time. Current recommendations are to administer the first dose of the HBV vaccine to every infant at birth and no later than hospital discharge. This policy eliminates the possibility of missed immunoprophylaxis in newborns of mothers who are HBsAg positive secondary to testing errors, ensures that newborns of mothers whose HBsAg status is unknown at delivery receive appropriate immunoprophylaxis, and reduces the risk of early childhood infection. This policy also protects infants who are discharged home to households with occult HBsAg-positive carriers and has been shown to significantly increase infant immunization completion rates.

### Hepatitis B–Negative Mother

Experts recommend that obstetricians and family physicians routinely screen all pregnant women for HBsAg during each pregnancy regardless of the presence or absence of risk factors and regardless of vaccination history. If the mother is HBsAg negative, then a single-antigen HBV vaccine (0.5 mL intramuscularly) should be given to the infant soon after birth and before discharge from the nursery. If the infant weighs less than 2 kilograms, then the first HBV vaccine dose is given at 30 days of chronologic age if medically stable or at hospital discharge before 30 days of chronologic age. After the birth dose the HBV series should be completed with either single-antigen HBV vaccine (Engerix or Recombivax) or a combination vaccine (Comvax or Pediarix). The second dose should be administered at age 1 to 2 months of age and the final dose at age 24 weeks or more of age. Administering 4 doses of HBV vaccine is permissible when combination vaccines are given after the birth dose.

### Hepatitis B–Positive Mother

If the mother is HBsAg positive, then the baby should receive hepatitis B immune globulin (HBIG; 0.5 mL intramuscularly) and HBV vaccine (0.5 mL intramuscularly) at separate sites within 12 hours of birth.

The HBV vaccination schedule should be completed on time, at 1 to 2 months and 6 months for single-antigen vaccine; at 2, 4, and 12 to 15 months for Comvax; or at 2, 4, and 6 months for Pediarix. Post-vaccination testing for HBsAg and anti-HBsAg should be performed at 9 to 18 months of age to assess immunity. If the newborn weighs less than 2 kilograms, then HBIG and HBV vaccine should be given within 12 hours of birth. However, this administration is not counted as the first dose; the full HBV vaccine series should be initiated at 1 to 2 months of age.

### Unknown Maternal Hepatitis B Status

If the mother's HBsAg status is unknown, then HBV vaccine (0.5 mL intramuscularly) should be given within 12 hours of birth. The mother should have blood drawn as soon as possible to determine her HBsAg status. If the mother is HBsAg positive, then the infant should receive HBIG as soon as possible (no later than 1 week). The HBV vaccination series should be completed on time, and postvaccination testing should be done at 9 to 18 months of age. If the newborn weighs less than 2 kilograms, then HBIG and HBV vaccine should be given within 12 hours of birth. This dose is not counted as the first dose, and the full HBV vaccine series is started at 1 to 2 months of age.

Transmission of perinatal HBV infection can be prevented in approximately 95% of newborns born to HBsAg-positive mothers by early active and passive immunoprophylaxis in the newborn by vaccine and HBIG. HBV vaccine alone, initiated at or shortly after birth, is also highly effective for preventing perinatal HBV infections. HBV vaccine is extremely cost effective not only in preventing HBV infection, but also in preventing the sequelae of chronic HBV infection. Therefore the first dose of HBV vaccine should be administered to every newborn at birth and no later than hospital discharge. This approach offers the best opportunity to prevent unrecognized perinatal transmission and to prevent transmission within families caused by unrecognized chronic HBV infection in the household. It places immunization as an early and visible priority for parents and offers added insurance that an overall immunization series will be completed on time.

### Infants Born to Mothers With Thyroid Disease

Neonatal thyroid function and health outcomes are influenced by maternal thyroid disease. Neonatal thyrotoxicosis is a rare condition caused by the transplacental passage of thyroid stimulating immunoglobulins from mothers with Graves disease or, more rarely, Hashimoto thyroiditis. Infants of mothers with Hashimoto thyroiditis should have the routine thyroid-stimulating hormone (TSH) measurement on day 3 or 4 (newborn blood spot screening [NBS]). The reported incidence of neonatal thyrotoxicosis among infants born to mothers with Graves disease is between 8% and 16%. Infants at risk of congenital hyperthyroidism (maternal Graves disease, family history of activating mutations in TSH receptor) should have the following

screening: Newborn screen between 2 and 5 days of age with a repeat screening test between 10 and 14 days of age. If a mother is on antithyroid medication, the infant should have more complete testing between 10 and 14 days of age, including free T4 (fT4), free T3 (fT3) and TSH.

## Chapter 88

# BREASTFEEDING THE NEWBORN

Lisa Stellwagen, MD; Richard J. Schanler, MD

## INTRODUCTION

Breastfeeding is nature's standard for infant nutrition and optimal health. Scientific evidence supports human milk feeding as important for mother and child. Pediatricians play a key role in supporting breastfeeding beginning at birth.

## BREASTFEEDING RATES IN THE UNITED STATES

In 1999, by mandate of Congress, the Centers for Disease Control and Prevention (CDC) began surveillance of breastfeeding rates through the National Immunization Survey.

The CDC "Breastfeeding Report Card" for the 2013 birth cohort tells us that 77% of all US women initiated breastfeeding, which is below the Healthy People 2020 objective of 82%, but showing steady gains every year. Although this period had the highest rates in recent years, only 37.7% were *exclusively* breastfeeding at 3 months. By 6 months of age only 49% of infants were receiving any human milk, well below the Healthy People 2020 goal of 61% ([www.cdc.gov/breastfeeding/pdf/2013breastfeedingreportcard.pdf](http://www.cdc.gov/breastfeeding/pdf/2013breastfeedingreportcard.pdf)). Considerable disparity exists among racial and ethnic groups. In the 2007 birth cohort, the tabulated data identified that breastfeeding rates for blacks were 60% for initiation and 28% at 6 months. This group, however, had the most rapid gains in breastfeeding rates in recent years (30% increase from 1996 to 2004). Breastfeeding rates for Latino or Hispanic mothers are greater than those of the total US population (approximately 81%). Although well below the national rates, significant increases in breastfeeding rates have also been reported for mothers 20 years of age or younger (60% initiation and 22% at 6 months), primiparous women, participants in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) (68% initiation and 34% at 6 months), and mothers of low-birth-weight infants. Breastfeeding rates at 1 year of age have only recently been measured. Whereas the Healthy People 2020 goal for 1 year is 34%, the total US rates in 2012 were 27%. In all populations, married, older, and highly educated women not working outside the home were more likely to initiate and sustain breastfeeding for longer durations.

National efforts are being focused on improving breastfeeding rates and programs to support mother and baby after delivery. The CDC are now collecting data on birth hospital indicators; in 2013 only 7% of infants were born in baby-friendly designated hospitals, and 24% of breastfeeding newborns receive formula in the first 2 days of life. Further efforts are being made by CDC to track maternity care practices that can effect mother/infant breastfeeding success; this National Survey of Maternity Practices in Infant

Nutrition and Care (mPINC) is being conducted every 2 years ([www.cdc.gov/breastfeeding/data/mpinc/index.htm](http://www.cdc.gov/breastfeeding/data/mpinc/index.htm)). Lastly, the CDC and Food and Drug Administration (FDA) are collaborating on the Infant Feeding Practices Survey II; this long-term study will follow mother and baby nutrition, infant feeding patterns, and determinants and benefits of breastfeeding ([www.cdc.gov/breastfeeding/data/infant\\_feeding.htm](http://www.cdc.gov/breastfeeding/data/infant_feeding.htm)).

Considerable need to overcome obstacles and continue breastfeeding-promotion efforts still exists to reach and maintain the modest goals set by the US Department of Health and Human Services in its Healthy People 2020 program. This effort is of particular importance for infant and maternal health because the populations at highest risk are the ones with the lowest breastfeeding rates and stand to gain the greatest health and developmental benefits from breastfeeding. The WIC program has made significant strides in increasing successful breastfeeding. Returning to employment or schooling outside the home by the mother is a major negative influence on both initiation and continuation of breastfeeding. National strategies are continuing to foster breastfeeding in the United States. The 2011 US Surgeon General's *Call to Action to Support Breastfeeding* ([www.surgeongeneral.gov/library/calls/breastfeeding/index.html](http://www.surgeongeneral.gov/library/calls/breastfeeding/index.html)) recommended a roadmap to improve support for breastfeeding mothers that focuses on the following areas:

- (1) *Mothers and their families* should be educated on the importance of breastfeeding, and be provided with ongoing support;
- (2) *Communities* must support breastfeeding, provide peer counseling support, and promote breastfeeding through community organizations and media, and remove all commercial barriers;
- (3) *Health care professionals* must adopt evidence-based practices (Baby-Friendly Hospital Initiative), provide health professional education, ensure access to lactation services, and increase availability of banked donor milk;
- (4) *Employers* must provide paid maternity leave and work-site accommodations;

- (5) *Research and surveillance* are needed and must be expanded, should address disparities, and measure the economic effect of breastfeeding; and

- (6) *Public health infrastructure* must demonstrate enhanced national leadership.

The Joint Commission (TJC) recently added the measure of in-hospital exclusive breastfeeding rates as a Perinatal Care Core Measure. TJC also promotes in-hospital breastfeeding to the public in their SpeakUp campaign. Pediatricians and other pediatric health care professionals should work with their hospitals to support successful breastfeeding initiation. (Box 88-1).

## BENEFITS OF BREASTFEEDING FOR THE INFANT

### Protective Effects

Breastfeeding provides significant benefits to both infant and mother (Box 88-2).

Understanding the benefits of human milk requires knowledge of the multitude of factors in mother's milk. Traditionally we have thought of breastmilk as nutrition with protein, fat, carbohydrate, and water as the principal components. But in reality human milk is more like a biologic fluid, containing hundreds of different biologically active factors: hormones, cytokines, growth factors, large amounts of secretory IgA, and numerous live maternal cells. Recent investigation confirms that human milk has probiotic bacteria as well as prebiotic factors that encourage optimal bacterial flora in the gut of the newborn. Indeed, human milk oligosaccharides are abundant and although not digested by the infant, serve to nourish probiotic bacteria. So it is not surprising that breastfeeding confers significant protection from infectious disease and inflammation in the young child. With improved data collection, these benefits have been looked at in a dose-response form, further adding to the evidence that longer periods of exclusive breastfeeding are optimal. The 2012 American Academy of Pediatrics policy statement on breastfeeding provides detailed information on these benefits (Table 88-1).

### BOX 88-1 Pediatrician Role in Breastfeeding Initiation

- Promote breastfeeding as the norm for infant feeding
  - Exclusive breastfeeding for about 6 months
  - Encourage continuing until at least 12 months of age
  - Add complementary foods at about 6 months of age
- Educate parents about the importance of breastmilk for all infants
  - Human milk and its components
  - Benefits of breastfeeding
  - Correct any false beliefs about infant feeding
- Prepare mother for hospital experience and recommend that:
  - Baby goes skin-to-skin at delivery
  - Erythromycin and vitamin K administration are recommended, but can be delayed up to 6 hours to allow for first nursing
- 24-hour rooming in is practiced
- Elective procedures (eg, bathing and circumcision) are delayed until infant is feeding well
- Encourage unrestricted nursing
  - Baby should nurse whenever interested; 8–12 times per day
  - Educate parents about norms in baby feeding, weight, stooling, and voiding
  - Avoid unnecessary supplements or pacifiers
  - Warn parents about common pitfalls
- Avoid any promotion of commercial infant formula or feeding equipment in your hospital or office

### Infectious Disease

Breastfed infants experience infectious illness at a lower rate than formula-fed infants, and the duration and severity of illness are shortened as well. These effects are observed in both developing and industrialized countries. Significant reductions in respiratory illness including hospitalization for lower respiratory tract infection, respiratory syncytial virus (RSV) severity, serious colds, and ear and throat infections are found in breastfed infants. Gastrointestinal tract infections are also greatly reduced, by 64%, in breastfed infants.

### SIDS Reduction

Breastfeeding has been shown in several large studies to be associated with protection against sudden infant death syndrome (SIDS), reducing the risk by half. Instructions to have the infant sleep in close proximity to mother, while avoiding bed sharing or falling asleep with the infant while nursing, should be a part of anticipatory guidance on safe sleep.

### Chronic Disease

Some epidemiological studies suggest that chronic pediatric disorders such as Crohn disease, leukemia,

## BOX 88-2 Rationale for Breastfeeding

### FOR THE INFANT

#### Reduces Acute Disorders

- Diarrhea and gastrointestinal infections
- Respiratory infections and hospitalizations
- Otitis media, acute and chronic
- Urinary tract infection
- Septicemia and bacterial meningitis
- Necrotizing enterocolitis
- Sudden infant death syndrome
- Postneonatal infant mortality

#### Reduces Chronic Disorders

- Insulin-dependent diabetes mellitus (type 1)
- Noninsulin-dependent diabetes mellitus (type 2)
- Obesity and overweight

- Allergy and asthma
- Inflammatory bowel disease (celiac and Crohn diseases)
- Childhood leukemia (acute lymphocytic leukemia and acute myelogenous leukemia)

### FOR THE MOTHER

- Decreases postpartum bleeding
- Facilitates postpartum weight loss
- Reduces stress hormone levels
- Provides contraceptive effect if used exclusively for 4–6 months
- Decreases risk of breast and ovarian cancer
- Decreases risk of type 2 diabetes mellitus
- Decreases risk of cardiovascular complications

In: Schanler RJ, Krebs NF, Mass SB, eds. *Breastfeeding Handbook for Physicians*. 2nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2014.

**Table 88-1** Dose-Response for Beneficial Effects of Breastfeeding

CONDITION	% LOWER RISK	COMMENT	OR	95% CI
Otitis media	50	EBF $\geq 6$ versus 3 mo	0.50	0.36–0.70
Recurrent otitis media	49	EBF $\geq 6$ versus 4–6 mo	0.51	0.28–0.94
Upper respiratory tract infection	70	EBF $> 6$ versus $< 6$ mo	0.30	0.18–0.74
Lower respiratory tract infection	77	EBF 4–6 versus $\geq 6$ mo	0.23	0.07–0.79
Asthma	40	EBF $\geq 3$ mo, positive atopic family hx	0.60	0.43–0.82
Asthma	27	EBF $\geq 3$ mo, negative atopic family hx	0.73	0.60–0.92
RSV bronchiolitis	74	EBF $> 4$ mo	0.26	0.07–0.90
Necrotizing enterocolitis	77	Exclusive human milk diet	0.23	0.51–0.94
Atopic dermatitis	27	EBF $> 3$ mo, negative family hx	0.84	0.59–1.19
Atopic dermatitis	42	EBF $> 3$ mo, positive family hx	0.58	0.41–0.92
Gastroenteritis	64	Any	0.36	0.32–0.40
Inflammatory bowel disease	31	Any	0.69	0.51–0.94
Obesity	24	Any	0.76	0.67–0.86
Celiac disease	52	$> 2$ mo gluten exposure when BF	0.48	0.40–0.89
Type 1 diabetes	30	EBF $> 3$ mo	0.71	0.54–0.93
Type 2 diabetes	40	Any	0.61	0.44–0.85
Leukemia (ALL)	20	$> 6$ mo	0.80	0.71–0.91
Leukemia (AML)	15	$> 6$ mo	0.85	0.73–0.98
Sudden infant death syndrome	73	EBF	0.27	0.24–0.31

Note: Percent lower risk refers to lower risk while breastfeeding compared with feeding commercial infant formula or referent group specified.

ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; CI, confidence interval; EBF, exclusive breastfeeding; hx, history; OR, odds ratio; RSV, respiratory syncytial virus.

From American Academy of Pediatrics Section on Breastfeeding. Breastfeeding and the use of human milk. *Pediatrics*. 2012;129(3):e827–e841.

lymphoma, and celiac disease occur less often among children who were breastfed as infants. Reduction in celiac disease development by as much as 50% occurs in babies who were breastfeeding when they were first exposed to gluten.

### Allergy

Reductions in clinical asthma and atopic dermatitis, especially in children with a family history of allergy, are seen in exclusively breastfed infants.

### Diabetes

Reduced rates of both type I and II diabetes have been reported for breastfeeding infants. Exposure, especially of high-risk individuals, to cow's milk protein early in life may play a role in the development of islet cell autoantibodies.

### Obesity

Obesity rates are lower in breastfed children, but the amount of protection is not clear. Estimates are that breastfeeding in infancy confers a 15% to 30% reduction in adolescent and adult obesity rates. This benefit may be a result of what breastfed infants are fed, but also how they are fed, since bottle-fed infants take in higher volumes and have been found to gain more weight in the first year of life.

### Premature Infants

For the premature infant, human milk protection against necrotizing enterocolitis and improvement in neurodevelopmental outcomes may be of great importance.

### Other Benefits

Maternal-infant bonding is enhanced during breastfeeding. Some studies indicate a dose-response relationship with IQ, the longer the duration of breastfeeding being associated with a higher cognitive score. The positive effects of breastfeeding on subsequent school performance have been reported into adolescence. Visual acuity, particularly in premature infants, seems to be enhanced by breastfeeding compared with formula feeding. Long-chain polyunsaturated fatty acids have been implicated as factors associated with better visual acuity in breastfed infants. The visual acuity of the breastfed infant is the model for studies of long-chain polyunsaturated fatty acid supplementation. Breastfeeding also provides analgesia to infants during painful procedures. Economic models suggest that the magnitude of health benefits is such that if all US mothers exclusively breastfed for 6 months, there could be a cost savings of \$13 billion per year.

## BENEFITS OF BREASTFEEDING FOR THE MOTHER

A tendency exists to assume that only infants and children benefit from breastfeeding. However, there are many positive effects of breastfeeding for the mother as well.

Breastfeeding in the first hour after delivery increases uterine contractility, reducing maternal blood loss and leading to more rapid involution of the

uterus. Postpartum weight loss may be facilitated in breastfeeding women. Several studies indicate that the greatest effect on weight loss occurs when the duration of breastfeeding exceeds 6 months. Psychological advantages to breastfeeding are obvious, given that bonding is fostered and quiet time is enforced on the nursing mother. Human data show decreased levels of adrenocorticotrophic hormone and corticosterone in lactating women. The blunted response of stress hormones may be an adaptive mechanism for the stress of labor and delivery. Exclusive breastfeeding delays the resumption of normal ovarian cycles and the return of fertility in most mothers. As such, the contraceptive effects of breastfeeding contribute globally to increased child spacing. Amenorrhea is most likely to occur in women who are exclusively breastfeeding, particularly in the first 6 months postpartum, which allows for repletion of maternal iron stores and correction of anemia. World epidemiological data indicate that prolonged breastfeeding into the second year, but not exclusively beyond 6 months, prolongs the interpregnancy interval to 1 year, resulting in the birth of the next infant 20 to 24 months after the previous infant. This longer interval may be a factor in reducing infant mortality.

Women who have a cumulative breastfeeding experience of 12 months have a 28% reduction in the rate of premenopausal breast and ovarian cancer. Each year of breastfeeding reduces a woman's risk of breast cancer by 4.3%. Additionally, women with a total lactation experience of 12 to 23 months enjoy additional reductions in hypertension, hyperlipidemia, cardiovascular disease, and diabetes. Losses in bone density (approximately 5%) are seen during lactation, with remineralization occurring during weaning. Researchers have suggested that the repeated cycles of demineralization-remineralization may strengthen bone.

Informing women and their partners that mother and baby benefit greatly from breastfeeding, and that longer periods of lactation may be even more protective, should be part of standard anticipatory guidance.

## SUPPORTING BREASTFEEDING: PRENATAL VISIT

The successful management of lactation begins during pregnancy. The prenatal office visit is an ideal time to encourage breastfeeding and to provide information so families can make an informed choice regarding infant feeding. Although some studies have shown that infant feeding decisions are made before the third trimester, choices may have been influenced by certain misconceptions or fears held by the expectant mother or father, such as fear of inadequate milk supply because of small breast size, possible loss of sexual breast activity during lactation, cosmetic breast changes as a result of lactation, being a failure at breastfeeding, beliefs that breast milk is not rich enough, and difficulties in learning how to breastfeed, as well as disapproval by the spouse, poor public acceptance, and possible loss of freedom or spontaneity. Many women express an intent to combination (breast and formula) feed their infants. This has been shown to shorten the duration of breastfeeding.

Because decisions are generally made early and few women have pediatric office visits prenatally, the early obstetric visit must take advantage of the opportunity to discuss and promote breastfeeding. As such, during the initial breast examination at an early obstetric visit, the mother should be commended on her choice of breastfeeding and reassured that her breasts are normal.

## SUPPORTING BREASTFEEDING: AFTER DELIVERY

While breastfeeding decisions are often made early, these decisions have been shown to be flexible, and ideal hospital support systems, including the Baby Friendly Hospital Initiative, have been successful at increasing breastfeeding initiation rates. The 10 steps that serve as the foundation for the WHO/UNICEF Baby Friendly Hospital Initiative to ensure breastfeeding success in the hospital are outlined in Box 88-3. The early days of lactation are critical to establishing a good milk supply and proper infant feeding. Many mothers who intend to exclusively breastfeed their babies are not successful, and adherence to the 10 steps may help a mother reach her goals. Education of family and staff, encouragement of exclusive breastfeeding, keeping mother and baby together, discouraging unnecessary supplements, provision of community resources, and close follow up of mother and baby after discharge may help to improve breastfeeding outcomes.

### Initiating Breastfeeding

Early initiation of breastfeeding within the first hour after birth should be practiced unless the medical

condition of the mother or infant indicates otherwise. Early nursing in the delivery room is associated with a marked increase in the percentage of mothers who continue breastfeeding at 2 to 4 months postpartum compared with initiation of nursing 2 hours after birth. Successful lactation management includes encouraging skin-to-skin contact and nursing in the delivery room, and keeping mother and baby together after delivery and during the hospital stay.

Although many infants placed on the mother's chest or abdomen during their usually alert and active first hour after delivery will spontaneously find the mother's nipple and latch on to it, others may require assistance. Eye prophylaxis, vitamin K administration, weighing, and other procedures can be performed after the first breastfeed has been achieved (Vitamin K can be delayed up to 6 hours after birth). Infant bathing is not necessary and may interfere with transition, early breastfeeding attempts, and adaptation of the neonatal skin.

### Position and Latch

The nursing mother can use many different positions. However, regardless of position, she should be comfortable (Figure 88-1). The football or cross cradle positions may provide an advantage for mothers who have undergone cesarean delivery, have a small or premature infant, or an infant who is having trouble latching on. These positions allow for good control of the infant's head, visibility of the infant's mouth on the breast, and avoid contact with mother's incision.

Mothers should understand the importance of achieving a proper latch (Figure 88-2). Note that a mother's fingers should be parallel to the infant's jaws and placed well behind the areola. This hand position allows her to compress her breast to facilitate milk transfer. A link to a complete breastfeeding guide for mothers is included in the Tools for Practice section at the end of this chapter.

If the infant has a deep latch and is sucking well, a mother will be comfortable and milk transfer will be optimized. The buccal mucosa and tongue mold around the breast, leaving no space. The milk is extracted by negative pressure generated from downward movement of the infant's tongue. When the infant is latched correctly, the mother will feel a gentle undulating motion or tugging but no pain with each suck.

If the latch is painful, to prevent additional nipple trauma, the mother can release the suction by inserting her finger gently into the corner of the infant's mouth. After detachment, the nipple should be observed; it should be elongated and have no creases or areas of trauma. Other signs of incorrect latch include dimpling of the infant's cheeks during suckling, clicking noises, lips curled inward, frequent movement of the infant's head, lack of swallowing, and maternal complaint of pain. New fathers or partners can be helpful in looking for these signs of good positioning and latch. Poor latch-on can eventually lead to nipple trauma, pain, poor milk transfer, poor infant weight gain, and low milk supply.

### BOX 88-3 10 Steps to Successful Breastfeeding

- Step 1: Have a written breastfeeding policy that is routinely communicated to all health care staff.
- Step 2: Train all health care staff in skills necessary to implement this policy.
- Step 3: Inform all pregnant women about the benefits and management of breastfeeding.
- Step 4: Help mothers initiate breastfeeding within 1 hour of birth.
- Step 5: Show mothers how to breastfeed and how to maintain lactation even if they are separated from their infants.
- Step 6: Give newborns no food or drink other than human milk, unless medically indicated.
- Step 7: Practice rooming-in—allow mothers and infants to remain together—24 hours a day.
- Step 8: Encourage breastfeeding on demand.
- Step 9: Give no artificial teats or pacifiers to breastfeeding infants.
- Step 10: Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

**Figure 88-1** Cross cradle (A) or football (B, C) positions help the mother properly position the infant and visually check the latch. (From *Get Ready to Breastfeed*. UC San Diego Health System Mother's Breastfeeding Guide and Log Book.)

### Signs of Milk Transfer

Once the infant is latched to the breast, suckling begins with rapid bursts and intermittent pauses. This action will assist with stimulating the milk ejection reflex. As milk flow is established, the rhythm of suckling, swallowing, and pauses becomes slower and more rhythmic, approximately 1 suckle or swallow per second. Audible swallowing indicates milk transfer to the infant. Swallowing may be difficult to hear when the newborn is taking small sips of

colostrum, but as milk volume increases, swallowing should be heard easily, sounding like “kuh.” At the end of nursing, the infant will often come off the breast spontaneously and if the feeding is adequate, the infant should seem content. As a mother's milk comes in, she should appreciate that her breasts are heavier and fuller before the feeding begins then softer and lighter after feeding is completed; this difference indicates that her infant has emptied her breasts.

**Figure 88-2** Achieving a good latch is key to the mother's comfort and to milk transfer. Note that the mother's fingers are well back on the breast (A) as the infant gapes wide. Avoiding a shallow latch (B) and aiming for a wide, deep latch (C) is the mother's goal. (From *Get Baby on the Breast / Got It Right?* UC San Diego Health System Mother's Breastfeeding Guide and Log Book.)

### Feeding at the Breast Versus Bottle

A distinct difference exists between tongue and jaw movements of breastfeeding and bottle-feeding infants. In breastfeeding, breathing is coordinated with sucking and swallowing, usually in a 1:1:1 pattern. The rapid flow from a bottle may result in respiratory pause and shortened expiration. A common assumption is that breastfed infants who have difficulty obtaining milk will be more likely to prefer bottle feeding if given the opportunity. Some infants may simply prefer the more rapid, gravity-induced flow from a bottle. Because the introduction of a bottle has the potential to disrupt the development of effective breastfeeding behavior, its use should be minimized until breastfeeding is well established.

### Hunger Cues

Many new parents expect their baby to cry when hungry, so they need to be informed that crying is a late sign of hunger and can result in an infant who is difficult to calm and latch to the breast. Anticipatory guidance and rooming in 24 hours a day allows the parents to notice early infant hunger cues, such as increased alertness, flexion of the extremities, mouth and tongue movements, cooing sounds, rooting, bringing the fist toward the mouth, or sucking on fingers or the hand. Signs of satiety also need to be taught, such as non-nutritive sucking with longer pauses between sucking bursts, self-release from the breast, disappearance of hunger cues, relaxed posture, and sleep.

### Feeding Norms

Colostrum is present in small amounts and an infant may desire to suck for a long time or nurse frequently. A mother should be encouraged to follow her baby's lead and refrain from timing or scheduling feeds. Once her milk is abundant, she should try to offer both breasts at each feeding. Falling asleep after the first breast and refusing the second is normal for a newborn. Allowing an infant to drain the first breast before switching to the other breast is preferable. A feeding should not be interrupted just to switch to the second side. Typically, the infant will spontaneously release the first breast after sufficient milk transfer.

Maternal milk supply evolves over the first days of lactation, and feeding frequency will change accordingly. Infants may be sleepy or hungry during the first 24 hours as they recover from the birth process; less frequent small feedings are often seen. Many infants have a transient neonatal ileus as they initiate feeding, active peristalsis and bowel movements. Parents can be reassured that the gagging, spitting clear mucous, and slight abdominal distention will generally abate by 24 hours. Mothers should be told that infant feeding drives their milk supply, and that after the infant is 24 hours old, 8 to 12 feedings a day will help to ensure good milk volumes (Table 88-2). Mothers who are aware that their milk volume is low the first day and increases step wise over the next few days will have more reasonable expectations regarding infant feeding frequency. Understanding infant hunger cues and preparing parents for disorganized nocturnal behavior ("second night syndrome") on the second or third nights after birth can minimize requests for unnecessary formula. Healthy breastfeeding babies do not need water, glucose water, or formula, and unnecessary supplements can interfere with successful breastfeeding.

### Separation

If mother and baby are separated because of the infant's admission to the neonatal intensive care unit, she will need to begin to express her milk. While hand expression should be taught to all breastfeeding mothers, using a double electric breast pump generally leads to higher milk volumes. Milk expressed by mother can be used to feed the infant and will help her in establishing and maintaining her milk production until baby is ready to breastfeed.

### Pacifiers

The use of pacifiers in the early breastfeeding period has been thought to be associated with shorter breastfeeding duration, although the evidence is still not clear. Avoiding pacifiers and other missed opportunities to breastfeed will help mother and baby get off to the best start. Pacifiers have been recommended to decrease the risk of SIDS and may be introduced after breastfeeding is well established, generally at 4 weeks of age.

Table 88-2 Breastfed Newborns Input/Output Norms

DAY OF LIFE	AGE IN HOURS	MILK VOLUME			# FEEDS	# VOIDS <sup>a</sup>	# STOOLS <sup>a,b</sup>	COLOR OF STOOLS	WEIGHT LOSS NORMS <sup>c</sup>	EXCESS WEIGHT LOSS <sup>c</sup>	SUPPLEMENT VOLUME
		MILK VOLUME PER FEEDING	PER FEEDING (MOTHER'S PERSPECTIVE)	MILK VOLUME PER FEEDING							
1	0-24	0-5 ml	drops		6-8	≥1	≥1	Meconium	Birth weight		5-10 ml
2	24-48	5-10 ml	1 tsp		≥8 <sup>d</sup>	≥2	≥2	Meconium	≤3%	>5%	10-20 ml
3	48-72	10-20 ml	1 Tbsp		≥8 <sup>d</sup>	≥3	≥3	Transitional	≤6%	>8%	20-30 ml
4	72-96	20-30 ml	1 oz		≥8	≥4	≥4	Transitional	≤8% (may gain)	>10%	30-40 ml
5	>96	>30 ml	>1 oz		≥8	≥4-12	≥4-12	Yellow	Baby should gain	>10%	40-50 ml

<sup>a</sup>Infant has 24 hours to void and 48 hours to stool after birth.

<sup>b</sup>There may be a lull in stooling after meconium is cleared while baby waits for increased milk volume.

<sup>c</sup>Weight loss norms and excess weight loss numbers are approximations and may be different for more robust or more vulnerable infants.

<sup>d</sup>Infants may feed very frequently (even hourly for the first few nights) before the milk comes in.

## ASSESSING THE BREASTFEEDING INFANT

### History

Maternal history, delivery, gestational age assessment, and infant growth parameters should be reviewed. Risk factors that might herald lactation problems should be queried (Box 88-4 and Box 88-5).

#### BOX 88-4 Mothers Who May Need Help to Successfully Breastfeed

- Intention to breast and bottle feed
- Lack of family or social support
- Psychological problems
- History of poor breastfeeding experience in the past
- Teen mother or advanced maternal age
- Presence of risk factors for poor or delayed milk production (eg, breast surgery, no breast changes in pregnancy, hypoplastic breasts)
- History of medical problems (eg, diabetes, obesity, hypertension)
- Use of medications that may effect milk production or have potential adverse effects on infant
- Perinatal complications (eg, hypertension, blood loss, infection)
- Cesarean section delivery
- Risk factors for latch problems (eg, flat or inverted nipples)
- Mother-baby separation after delivery

#### BOX 88-5 Infants Who May Need Help to Successfully Breastfeed

##### VULNERABLE INFANT

- Late preterm infants (34–36 weeks gestation)
- Multiple births
- Intrauterine growth restricted infants with low reserve
- Hypotonic infant (eg, trisomy 21, achondroplasia)
- Abnormal oral anatomy (eg, cleft palate, ankyloglossia, micrognathia)
- Resuscitation at birth, poor transition, or prolonged labor

##### MEDICAL COMPLICATIONS

- Hyperbilirubinemia
- Hypoglycemia
- Infection/at risk for sepsis
- Birth trauma
- Excessive weight loss/dehydration

##### SUBOPTIMAL FEEDING IN HOSPITAL

- Failure to latch in first 24 hours
- Poor or uncoordinated suck
- Sleepy or infrequent feeder

### Physical Examination

Physical examination of the infant should include an oral-motor examination, with visual inspection of the palate and lingual frenulum. A digital assessment of suck with a gloved finger is invaluable to detect abnormalities in suction pressure, jaw laxity, or tongue movement. Presence of congenital anomalies, tone abnormalities, torticollis, or other physical factors that could effect feeding capabilities should be noted.

### Weight Loss Norms

All breastfed infants lose weight for several days after birth; indeed, even bottle-fed infants do. While feeding volumes are low for the first 24 to 72 hours, infants have obligatory urinary loss and must eliminate the meconium stool. Exact norms in weight loss vary by feeding method, and studies are complicated by traditions of formula use in newborns. However, a weight loss of 3% per day is deemed normal over the first days, and a total weight loss of 6% to 8% by day of life 3 to 4 is commonly seen. Once mother's milk is abundant (generally after 96 hours), the infant should begin to gain weight, at least 15 to 30 g (0.5–1 oz) per day. At this rate, most breastfed infants will exceed their birth weight by 7 to 14 days and gain 150 to 210 g/week (5–7 oz/week) for the first 2 months.

### Elimination Norms

After the first few days, patterns of stooling and voiding are good indicators of the adequacy of milk intake. Urination may be infrequent at first because of the relative dehydration of the baby, but immature renal concentrating ability may result in a baby continuing to void despite dehydration. Urine may initially be dark or contain uric acid crystals, but by day 4 or 5, an infant should pass 6 or more clear, dilute urines each day. Initial elimination of meconium may be unrelated to feeding, but the transition to breast-milk stool is a key indicator of intake. Once an infant has a good milk intake, the stool will begin to transition in color from black to brown to green and then to yellow seedy stools by day 4 or 5 of life. Anticipatory guidance is helpful because stools of the normal human milk-fed newborn are often loose and may be confused with diarrhea if parents are accustomed to seeing the firm, brown stools typical of formula-fed infants. Parents can be told to watch for minimums of 1, 2, and 3 wet and soiled diapers on day of life 1, 2, and 3, respectively. Thereafter, well-nourished breastfed infants usually pass a medium-sized yellow stool at least 3 to 4 times a day, or as often as with every feeding.

A logbook kept by the mother recording feeding and elimination by the infant in the first few weeks can be helpful (see Tools for Practice for a link to a complete breastfeeding guide and log book).

### Breastfeeding Observation

The physician should observe a feeding if any questions regarding adequacy of feeding exist. Alternatively, a trained lactation specialist should examine these couples to evaluate infant positioning at the breast, the ability of infant to latch, quality of latch, milk transfer, presence of audible swallowing, the anatomic and

**BOX 88-6 The First Postpartum Office Visit: 3 to 5 Days of Age (48–72 Hours After Discharge)****BREASTFEEDING ASSESSMENT**

- How many feedings, voids, and stools in past 24 hours?
- Does newborn need to be awakened to feed?
- Does newborn easily latch on to breast and nurse eagerly?
- Is newborn receiving any supplements?
- How is mother doing, and how is she feeling about breastfeeding?
- Are mother's breasts comfortable?
- Has mother previously breastfed?
- Is mother taking any medication?
- How is mother's nutrition?
- How do family members feel about breastfeeding?

**EXAMINING NEWBORN AND MOTHER**

- Calculate newborn's weight gain or loss since birth.
- Observe breastfeeding.
- Examine mother's breasts or refer for examination, if needed.
- Consider using test weight to estimate volume of milk transferred by newborn if concerns exist.
- Perform routine newborn and oral-motor examination.
- Assess state of hydration.
- Observe for jaundice.

**ANTICIPATORY GUIDANCE**

- Encourage breastfeeding on demand.
- Review normal breastfeeding and elimination patterns.

- Avoid long nighttime intervals without feeding.
- Review safe sleep and SIDS prevention.
- Ensure that infant is taking 400 IU of vitamin D.
- Reinforce the importance of the care of the mother.

**BREASTFEEDING INTERVENTIONS**

- Attempt to determine and treat the cause of inadequate milk supply before supplementing.
- For indicated supplementation, use adequate volume.
- If milk transfer is not optimal, mother should express to provide milk for baby.
- Discuss techniques to progress to exclusive breastfeeding.
- Consider referral to lactation specialist or support group if problems are ongoing.

**CLOSING THE VISIT**

- Congratulate parents on decision to breastfeed their newborn.
- Review some of the benefits of breastfeeding and risks of unnecessary supplementation.
- Remind mother to eat when hungry and drink when thirsty.
- Arrange for appropriate follow-up visit until weight gain is adequate and breastfeeding is going well.

physiologic characteristics of the nipple, maternal responses, and whether the caregiver needs to provide assistance with feeding. The hospital staff should observe and document their own breastfeeding observations in the medical record at least twice daily.

**Discharge From the Hospital**

The newborn infant and mother are often in the hospital 2 days after a vaginal delivery, and 3 to 4 days after cesarean delivery. However, discharge readiness of the infant is an important factor to consider prior to sending the couple home. Infants who have significant risk factors for failed breastfeeding, hyperbilirubinemia, or hospital readmission may need more time in the hospital. Increased attention to the morbidities of readmitted infants has led to recommendations that the infant meet minimal discharge criteria. Further observation may be required if the infant is low birth weight or born late preterm. Suggested criteria relative to breastfeeding include that the mother has the knowledge, confidence, and ability to care for the baby, and that the infant has accomplished the following: 2 successful consecutive feedings, coordination of suck-swallow-breathe during feeds, passed an assessment by trained staff for feeding adequacy, passed at least 1 stool, and has urinated regularly. Prior to discharge, infants should also have an assessment of hyperbilirubinemia risk. Consideration of weight loss criteria for discharge may be important. Infants with excessive weight loss should not be sent home without a detailed feeding plan.

**Post-discharge Assessment and Nutrition****Post-discharge Visit**

This first visit should occur 48 to 72 hours after discharge—at 3 to 5 days of life—and should be used to assess the adequacy of hydration, milk intake, and weight gain, the presence of jaundice, and the state of the mother (anxiety, concerns). Vulnerable infants, including late preterm infants, fragile feeders, and infants with excessive weight loss or jaundice may need to be seen 24 hours after discharge. Breastfeeding should be observed during this first visit if any concerns exist. (Box 88-6 provides a checklist for the first postpartum visit.) Telephone contact should be encouraged if further questions arise. Families should be made aware of the availability of community, office, and hospital lactation resources.

Resources exist to aid the pediatric practice with optimal breastfeeding support. The Academy of Breastfeeding Medicine (ABM) clinical protocol (*The Breastfeeding-Friendly Physician's Office*) has been shown to lead to higher rates of initiation and exclusive breastfeeding, and offers practical steps that can be adopted by a pediatric practice (see Box 88-7). The Safe and Healthy Beginnings Toolkit (referenced in Tools for Practice) provides materials to support breastfeeding in the jaundiced newborn.

**Growth Patterns of Breastfed Infants**

The conclusions drawn from plotting the growth of a breastfed infant on older growth charts may be

### BOX 88-7 Elements of a Baby-Friendly Physician's Office

1. Establish a written breastfeeding office policy.
2. Encourage exclusive breastfeeding.
3. Culturally competent care.
4. Offer a prenatal visit.
5. Collaborate with local hospital and the community.
6. Schedule newborn visit within 48–72 hours and provide access to a lactation consultant.
7. Provide educational resources.
8. Encourage open breastfeeding.
9. Discourage formula marketing.
10. Telephone support.
11. Commend breastfeeding.
12. Recommend exclusive breastfeeding to 6 months of age.
13. Work site lactation policy.
14. Establish community resources.
15. Insurance and billing.
16. Assist with workplace support.
17. Formal staff training and on-site IBCLC services.
18. Mentor health care providers.
19. Data tracking.

IBCLC, International Board Certified Lactation Consultant  
Adapted from Academy of Breastfeeding Medicine Protocol Committee.  
ABM Clinical Protocol #14: Breastfeeding-Friendly Physician's Office, Part 1:  
Optimizing Care for Infants and Children. *Breastfeed Med.* 2006;1:115–119.

erroneous if the chart does not adequately reflect the normal growth of the breastfeeding infant. Newer growth curves for exclusively breastfed infants, developed by the WHO, are available online ([www.cdc.gov/growthcharts/who\\_charts.htm](http://www.cdc.gov/growthcharts/who_charts.htm)).

Growth faltering is a concern when the weight for age (or weight for length) is more than 2 standard deviations below the mean or a weight for age that crosses more than 2 percentile channels downward on the growth chart. The WHO growth curve will assist in evaluating an infant whose growth is questionable. Assessments of milk supply and intake, appropriateness of complementary foods, the feeding environment, and the potential for micronutrient deficiencies (eg, iron, zinc, vitamin D) are all part of the nutritional assessment of the infant with slow weight gain or faltering linear growth. The principles in assessing insufficient milk syndrome should also be considered for these infants (see Primary Insufficient Milk Syndrome section).

#### Duration of Breastfeeding

The AAP recommends that infants be exclusively breastfed for about 6 months, followed by continued breastfeeding as complementary foods are introduced, with continuation of breastfeeding for 1 year or longer as mutually desired by mother and infant.

#### Vitamin D

Exclusive breastmilk feeding, highly prevalent maternal vitamin D deficiency, and recommendations to limit sun exposure in infants have led to an increased incidence of vitamin D deficiency. Recommended supplementation

of all breastfeeding newborns with 400 IU of vitamin D daily should start soon after birth.

#### Iron

Healthy term infants generally have sufficient iron stores to meet their needs until 4 to 6 months of age. Because human milk has low amounts of iron, the AAP recommends that exclusively breastfed term newborns be given an iron supplement of 1 mg/kg/day from 4 months of age until these needs can be met by the intake of complementary foods. Infants who have had blood loss at birth or are otherwise at risk for having low iron stores (late preterm infants, growth restricted infants, infants of diabetic mothers) may need earlier iron supplementation or monitoring of laboratory values to assess iron stores.

#### Complementary Foods

The timing of complementary foods introduction into the diet of the breastfed infant is difficult to define with precision, and indeed a single optimal age for all infants may not exist. The recommendations by the WHO and other organizations for exclusive breastfeeding for approximately 6 months are intended for populations and do not dictate the management for individual infants. The AAP recommends exclusive breastfeeding for about 6 months, while recognizing that some infants are developmentally ready to accept complementary foods before this time. Decisions about introducing complementary foods for individual infants need to be based on several considerations, including birth weight, postnatal growth rates, and developmental readiness. Infants who were born prematurely or small for gestational age may need micronutrients, especially iron and zinc, earlier than would be provided by complementary foods. Delay of introducing complementary foods beyond 6 months is not recommended because of increasing risk of micronutrient deficiencies.

### BREASTFEEDING INITIATION: SPECIAL CIRCUMSTANCES

Most women are able to establish and sustain breastfeeding for an extended period if they are motivated, have support from their families, employers, communities, and the medical system. Women with certain medical and psychosocial conditions may not succeed at breastfeeding, and in rare situations, an infant should not be breastfed (see Box 88-4 and Box 88-5).

#### Breast Size

Breast size is not an indicator of breastfeeding success. Small breast size is not a predictor of lactation failure because most of the breast mass is fat tissue, not glandular tissue. Thus even small breasts should have enough glandular tissue to produce sufficient milk. Breast maldevelopment, such as breast hypoplasia or tubular shaped breasts, has been associated with a high frequency of lactation failure and should prompt close monitoring of infant weight gain.

#### Breast Surgery

Breast surgery, whether for reduction or augmentation mammoplasty, removal of a mass, or as a result of trauma, may be a cause for breastfeeding difficulties. In

general, breast augmentation does not cause problems with the establishment of breastfeeding, unless surgery was performed for breast hypoplasia. Women who have had reduction mammoplasty with repositioning of the areolae and nipples are more likely to have difficulty producing adequate milk because of interruption of the ducts and subsequent blockage of milk flow. Newer surgical techniques may improve outcomes, but these mothers require close observation for milk production and monitoring of infant weight gain and hydration.

### Primary Insufficient Milk Syndrome

Breast enlargement during pregnancy is an important factor in predicting lactation success. Failure of breasts to enlarge during pregnancy often presages lactation failure. Approximately 5% of women will not produce adequate milk, known as *primary insufficient milk syndrome*. Generally, breastfeeding should be encouraged and attempted if the mother so desires. The possibility of difficulty in establishing lactation should be discussed with the mother. Additional assistance, monitoring of infant milk intake or weight gain, judicious use of supplemental feedings, and encouragement should be provided to optimize milk production and appropriate infant growth.

### Human Immunodeficiency Virus and Human T-Cell Lymphotropic Virus

Women in the United States who are infected with HIV or human T-cell lymphotropic virus type 1 should not breastfeed because of the risk of transmission to the nursing infant. In developing countries where infectious diseases and malnutrition are the predominant causes of infant mortality, the health risks of not breastfeeding must be balanced with the risk of HIV acquisition. More recent data suggest beneficial effects of breastfeeding in infants of HIV-positive mothers who are also receiving antiretroviral therapy, but no therapy eliminates the risk of transmission through breastmilk.

### Tuberculosis

Women with active pulmonary tuberculosis should not breastfeed until they have received appropriate antibiotic treatment for approximately 2 weeks and are no longer contagious, as determined by their physician or public health official. Because transmission of tuberculosis is primarily by respiratory tract droplet or airborne transmission, separating mother and baby is of primary importance. Whether the tubercle bacillus actually passes into the milk is unclear; most hospitals allow a mother to provide expressed milk to her infant.

### Varicella-Zoster Virus

Neonates should be given varicella-zoster immune globulin if their mothers develop varicella from 5 days before delivery to 2 days after delivery. These infants are separated from mother until her lesions are crusted over but can receive expressed breastmilk. Varicella vaccine may be given to susceptible breastfeeding mothers if the risk of exposure to natural varicella is high.

### Herpes Simplex Virus

Women with herpetic breast lesions should not breastfeed from the infected side until the lesions have healed, although expressed milk can be given to the infant. Proper hand washing and covering the lesions are recommended to prevent infant infection. Women with genital herpes can breastfeed.

### Hepatitis B

Breastfeeding by women who are hepatitis-B surface antigen-positive does not alter the risk of infant infection. Infants born to known hepatitis B-positive mothers should receive both hepatitis B vaccine and hepatitis-B immune globulin within 12 hours after birth. There is no need to delay breastfeeding for infant immunization.

### Hepatitis C

Hepatitis C virus and hepatitis C antibody have been detected in human milk. Infant acquisition of the virus through breastfeeding has not been reported. Maternal hepatitis C infection is not a contraindication to breastfeeding. Some advise abstinence from breastfeeding if the mother has cracked or bleeding nipples.

### Other Infectious Agents

*Cytomegalovirus* (CMV) may be shed in the milk of seropositive mothers. In healthy term infants, symptomatic CMV disease from transmission through human milk is uncommon. However, premature infants may be at greater risk of symptomatic disease characterized by sepsis-like syndromes. Because human milk is of great importance to the premature infant, most neonatal units continue to use milk of mothers who are known to be CMV positive or who have seroconverted during lactation. Pasteurization of milk may inactivate the virus and freezing may decrease but not eliminate viral content of mother's milk; either process may allow baby continued access to human milk. Long-term follow-up of the few premature infants who were presumed to have acquired CMV postnatally have found no abnormalities in brain imaging, hearing tests, and visual function studies.

*West Nile virus* has been detected in human milk but risks to the breastfed infant are not well understood.

*H1N1* virus in acutely infected women can be spread to infants. The CDC recommends that baby be separated from mother until she is afebrile, but may receive her expressed milk.

*Brucellosis* may be transmitted in human milk and infants of mothers with untreated disease should not receive human milk.

### Radiologic Procedures

Therapeutic radiographs, CT scans, and MRIs are not a problem for nursing mothers. Common contrast agents including iodinated intravenous agents or gadolinium are not excreted into milk in sufficient amounts to be problematic, and mothers should not be told to pump and dump their milk for these procedures. Mothers receiving diagnostic or therapeutic radioactive isotopes or who have had accidental exposure to radioactive materials should not breastfeed for as long as radioactivity in milk is present.

### Substance Abuse

Women ingesting drugs of abuse (amphetamine, cocaine, heroin, marijuana, phencyclidine) need counseling and should not breastfeed until their systems are free of the abused drugs that may harm the infant. Narcotic-addicted women who are in treatment may be encouraged to breastfeed if they have no other risk factors.

### Alcohol

Changes in infant feeding patterns have been reported in infants soon after mothers have ingested large amounts of alcohol quickly; it is among the few substances that achieves high concentrations in human milk. The AAP recommends mothers limit alcohol to occasional use of no more than 2 ounces of liquor, 8 ounces of wine, or 2 beers, and further recommend that nursing take place after more than 2 hours have elapsed since alcohol intake.

### Cigarette Smoking

Mothers should be discouraged from smoking during lactation. If a mother continues to smoke, breastfeeding should be encouraged for the protective effects in the infant, especially with respect to protection from respiratory illnesses and SIDS.

### Medications

Most medications are compatible with breastfeeding, or, if not compatible, a substitute medication may exist and should be sought.

Half a million pregnant women each year have been found to suffer from a psychiatric disorder. One in 6 pregnant women and up to 20% of postpartum women suffer from depression. Breastfeeding benefits mother and infant, but concerns exist about infant exposure to psychotropic medication. In general, sertraline, paroxetine, and fluvoxamine are felt to be compatible with breastfeeding, although little data exist on long-term effects. Other drugs should be reviewed for safety and alternative medication sought if concerns exist. The National Library of Medicine maintains an updated Web site (LACTMED) providing detailed information about safety profiles of maternal medication and breastfeeding ([toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT](http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT)).

### Cancer Therapy

Women with breast cancer should not delay treatment so they can breastfeed. Depending on the therapy, women receiving antimetabolite chemotherapy may be able to breastfeed by pumping and discarding their milk until the chemical has been cleared after each treatment. Radiation therapy is generally compatible with breastfeeding. Radiation treatment of the breast, however, may significantly damage sensitive breast tissue and be detrimental to future lactation performance of the affected breast.

### Inborn Errors of Metabolism

Infants with classic galactosemia (galactose-1-phosphate uridyl transferase deficiency) cannot ingest lactose-containing milk. Therefore, because lactose is the principal carbohydrate in human and bovine milk,

infants with classic galactosemia should not breastfeed nor receive formula containing lactose.

Infants with other inborn errors of metabolism may ingest some human milk, but this recommendation would depend on the desired protein intake and other factors. Phenylketonuria has been managed with a combination of partial breastfeeding and phenylalanine-free formula. Human milk contains relatively low levels of phenylalanine compared with formula.

## MATERNAL BREASTFEEDING ISSUES

### Nipple Pain

Sore nipples are the most common complaint of breastfeeding mothers in the immediate postpartum period. Early, mild nipple discomfort is common among breastfeeding women. Severe nipple pain, the presence of nipple trauma, pain that continues throughout a feeding, or pain that is not improving at the end of the first week should not be considered a normal part of breastfeeding. If ignored, nipple pain can then lead to other problems, such as engorgement, mastitis, low milk supply, early cessation of breastfeeding, and alterations in maternal mood or sleep.

Improper breastfeeding technique, specifically, poor position and improper latch, is the most common cause of nipple pain in the immediate postpartum period. Infant tongue-tie or generation of excessive suction pressures may also play a role. Limited milk transfer occurs when the infant is attached incorrectly, resulting in poor infant weight gain and impaired milk production. Limiting the time at the breast will not prevent nipple pain. Treatment for nipple pain depends on the underlying cause. Skilled help with position and latch-on are primary interventions. Frenotomy for tongue-tied infants seems to improve pain for many women. Specific infections and dermatoses require directed therapy. Pain relief medications may be needed. If severe trauma exists, then either manually or mechanically expressing milk may be necessary until the tissue has healed well enough to resume breastfeeding. Nipple healing may be hastened if a small amount of breastmilk is applied to the area after a feeding.

### Delayed or Insufficient Milk Production

Abnormalities in milk production, whether in amount or timing, are problematic because they can lead to excessive weight loss in the infant and early weaning. Identification of women who are at high risk for milk delays and close monitoring of infant weight loss can prevent later problems.

Women can have delayed onset of milk production for many reasons. Brief delays are often seen in mothers who are older, obese, diabetic, hypertensive, had cesarean section, have a history of infertility, or have infants who did not nurse well in the early days after delivery. Other risk factors for delayed milk production include higher postpartum fluid balance and postpartum edema. Factors that decrease breast stimulation, such as unnecessary formula supplementation, mother baby separation or missed feedings, can also cause delays. Recent reports have found that as

many as 44% of primiparous mothers have milk delay, although 98% of mothers eventually produce adequate supply by 7 days postdelivery.

Identifying the etiology of the delay and treating the primary problem is key. Initiating human milk expression for infants who are not feeding well, or brief formula supplementation of infant until mother's milk is in may preserve breastfeeding.

Rarely, mothers have primary lactational failure because of inadequate glandular tissue or hormonal factors. Characteristically these women have a lack of breast growth during pregnancy and may have abnormal breast appearance. Mothers who have had breast surgery are also at risk of insufficient milk transfer, especially if afferent nerves or ducts have been severed. Identifying these mothers before infant discharge is important to prevent dehydration and failure to thrive.

Low milk production may also result if infant does not empty the full breast. Treatment in this case involves expressing milk to feed the infant and to stimulate increased milk production by completely emptying breasts. A full or engorged breast leads to accumulation of serotonin, which is a feedback inhibitor of milk production.

The major goal in management for all of these conditions is to increase milk production, improve milk transfer, and most importantly, to adequately feed the baby.

### Engorgement

Physiologic breast fullness occurs because of vascular congestion during milk production. Pathological engorgement is the firm, diffuse, and painful overfilling and edema of breasts usually caused by inadequate milk removal. If left untreated, engorgement may then lead to difficulties in latch or mastitis. Engorgement may also occur later in the course of breastfeeding related to a missed feeding or an abrupt change in feeding frequency. The swelling and tenderness of engorged breasts are bilateral and generalized, and the condition is rarely associated with high fever or systemic symptoms. The primary treatment is frequent and effective milk removal, by baby or mechanical expression.

### Plugged Ducts

A plugged duct is a localized blockage of milk, often characterized by a painful mass in the breast. This lump may decrease in size with nursing. The condition may be caused by an abrupt change in the feeding schedule, inadequate draining of the breast, failure to vary nursing positions, or wearing tight and constricting clothing (such as a poorly fitting under-wire bra). Some anatomic variations may lead to plugged ducts, especially when the condition recurs in the same breast segment. Rarely, what is considered a plugged duct may be a tumor, benign or malignant, that is blocking the duct. Plugged ducts are easily differentiated from engorgement or mastitis and are not associated with fever or other signs of systemic illness. The treatment for plugged ducts is to apply moist heat before feeding and massage the affected area before and during nursing.

### Mastitis

Mastitis is a unilateral bacterial infection of the breast. Mastitis most commonly produces a single area of localized warmth, tenderness, edema, and erythema in 1 breast more than 10 days after delivery. The infection may be accompanied by a sudden onset of breast pain, myalgia, and fever or with influenza-like symptoms such as fatigue, nausea, vomiting, and headache. Milk stasis resulting from engorgement, obstruction of milk ducts from plugged ducts, or a cracked nipple can lead to mastitis. Most of the causative organisms are penicillin-resistant *Staphylococcus aureus*. The treatment of mastitis includes antibiotics for a 10- to 14-day course; additional therapy includes adequate fluid intake, bed rest, and pain control. Breastfeeding should continue during treatment to allow drainage of the infected breast; this does not pose a risk to the infant. Manual expression or a breast pump may be needed to remove the milk from the breast if severe pain precludes breastfeeding. If surgical drainage of a breast abscess is required, interruption of nursing on the affected breast may be necessary for 24 to 48 hours. However, mother should pump that side and continue nursing on the unaffected breast.

## NEONATAL ISSUES AND BREASTFEEDING

### Hypoglycemia

Hypoglycemia is among physicians' most commonly cited concerns regarding breastfed infants, but healthy term infants with normal feeding patterns have adaptations in place to prevent problematic hypoglycemia. Breastfed infants are known to have lower blood glucose and higher ketone levels than formula-fed infants. Minimizing cold stress by encouraging skin-to-skin care and improving milk intake by early and frequent breastfeeding may decrease hypoglycemia in healthy newborns. Infants who are small or large for gestational age, late preterm, or born to diabetic mothers are most commonly affected by hypoglycemia in the normal newborn population. Screening for hypoglycemia is recommended in symptomatic or at-risk infants only. Current recommendations suggest responding to mild hypoglycemia with prompt feeding (breast, expressed milk, or formula) and treatment with intravenous glucose if infant does not respond to feeding or becomes symptomatic. Routine supplementation of healthy, asymptomatic breastfed infants to prevent hypoglycemia is not indicated.

### Excessive Weight Loss

Healthy term exclusively breastfed infants lose an average of 6% of their body weight in the first 2 days of life. Most infants thereafter lose only another 1% to 2% as mother's milk comes in and commonly will start to gain weight on day 4 or 5 of life. Weight loss of 10% can lead to dehydration, hypernatremia, hyperbilirubinemia, and poor feeding. Recent studies show that many exclusively breastfed babies are losing too much weight—up to 19% of newborns had weight loss of 10% or more. Weight loss in the first days are likely multifactorial, and may reflect poor feeding, low milk supply, and excessive maternal and infant hydration, among other causes. Infants who are at risk for excessive weight loss may

show greater loss early; losing 5% of birth weight in the first day predicts an ultimate 10% weight loss. Predictors of excessive weight loss are not surprisingly similar to risk factors for delayed onset of milk production, which is known to happen in as much as 42% of women and increases the risk of excessive weight loss 7-fold in the infant. Poor breastfeeding in the first day of life triples the risk for excessive weight loss. Current trends in maternal medical complications—including obesity, diabetes, older maternal age, multiple births, hypertension, and cesarean section rates of 35%—are leading to an increased prevalence of delayed maternal milk production and perhaps are contributing to more infants with excessive weight loss.

Practical assessment of an infant's weight loss and fluid status while in the hospital involves reviewing correctness of birth weight and daily weights, baby's feeding ability, maternal milk production/breast fullness, and baby's urination and stooling progression, as well as any complicating medical factors. Assessment of milk transfer to the baby by performing a pre- and post-feeding weight can give valuable information to make a proper feeding plan. Initiation of formula supplementation for excessive weight loss, milk delay or infant medical reasons should be done by looking at the whole picture and discussing risks and benefits with the family. Discharging a newborn with excessive weight loss from the hospital should be done cautiously. A baby with weight loss of 10% or more may be hypernatremic and have secondary poor feeding, and may be at high risk for readmission and hyperbilirubinemia. It may be wise to keep the baby another day to demonstrate weight gain, improved feeding behavior, and good milk transfer.

Once the baby begins to gain weight, expect to see 30 g of weight gain per day, although gains of 100 g per day are common when mother's milk is abundant and infant is feeding well. A breastfed infant who weighs less than birth weight at 2 weeks requires evaluation and intervention.

### Supplementation of Breastfeeding

Breastfed newborns may require supplements of expressed milk, pasteurized donor milk, or formula for several medical conditions. Routine supplements without medical indications are not advisable and may lead to early termination of breastfeeding. Supplements of water, glucose water, or soy formulas have no role in the feeding of healthy term newborns. Parents who insist on supplementing their baby, if it isn't necessary, should be informed of the risks, but allowed to make the final decision for their child.

Box 88-8 details some common reasons for supplementation in a checklist form. Using a stamp or checklist in the chart or electronic medical record for the documentation of necessity and method of feeding may decrease the use of unnecessary supplements.

Much controversy exists over the best method to supplement babies that require additional milk. Many hospitals prefer to avoid the bottle and use a cup or tube at the breast. Allowing baby to receive the supplement at the breast controls the flow of milk, keeps baby oriented to mother's breast, and continues her breast stimulation. Some, but not all, infants may become difficult to nurse after using a bottle nipple.

#### BOX 88-8 Indication for Supplementation of Breastfeeding

Supplementation initiated for:

- ☐ Hypoglycemia: glucose \_\_ mg%
- ☐ Excessive wt loss: \_\_% at \_\_ hours of age
- ☐ Failure to latch at \_\_ hours
- ☐ Delayed milk production
- ☐ Jaundice related to decreased intake (per provider)
- ☐ LBW/IUGR requiring caloric supplementation (per provider or LC)
- ☐ Mother/baby separation; please explain \_\_\_\_\_

☐ Maternal insistence

☐ Other

Education provided re: risks & benefits of formula: YES NO

If NO, explain: \_\_\_\_\_

Supplement given (check all that apply)

- ☐ Expressed breastmilk \_\_ ml
- ☐ Pasteurized donor human milk \_\_ ml
- ☐ Commercial infant formula \_\_ ml
- ☐ Tube at breast
- ☐ Finger
- ☐ Cup
- ☐ Bottle

Mother pumping? YES NO

If NO, explain: \_\_\_\_\_

Supplementing infants with small volumes, appropriate for their age and size may prevent overfeeding, development of ileus in the first 24 hours of life, and allow for ongoing frequent feedings. Suggested volumes shown in Table 88-2 are extrapolated from normal maternal milk production values in the first days of lactation. Tailoring the supplement to each infant's caloric and fluid needs is important, and feeding volumes should be individualized.

Supplement nutrient should always be mother's expressed milk if it is available. While some hospitals offer families access to pasteurized donor human milk from a milk bank, supplies are limited, and donated milk from friends and family is discouraged for safety issues. For mothers with delayed or insufficient milk, the temporary use of a standard term (cow's milk based) infant formula is suggested. Families wishing to avoid cow's milk protein formula can use a hypoallergenic or elemental formula if desired.

### Late Preterm Infants

Infants born at 34 to 36 <sup>6</sup>/<sub>7</sub> weeks are known to be at high risk for feeding problems and hyperbilirubinemia. These infants, if they remain with the mother in couplet care (not in the NICU), may be at additional risk of readmission and poor feeding outcomes. Identification of these infants as fragile feeders, and hospital policies that encourage extra breastfeeding

support, observation for feeding success, monitoring for jaundice, and assessment of discharge readiness, may help to decrease these morbidities.

### Jaundice

The association between breastfeeding and jaundice is observed in 2 distinct entities: *breastfeeding jaundice* and *breast milk jaundice* (see also Chapter 99, Neonatal Jaundice).

#### Breastfeeding Jaundice

Breastfed newborns will often be found to have elevated bilirubin in the first week of life. However, we now know that breastfed infants who are feeding frequently and obtaining proper amounts of mother's milk, will have the same bilirubin levels as formula-fed infants. Infants who are not feeding well are at risk for breastfeeding jaundice, which is essentially a form of starvation jaundice. The combination of low milk intake, relative dehydration, delayed passage of bilirubin-rich meconium, and an active enterohepatic circulation of bile may lead to this phenomenon. Infants with increased rates of bilirubin production caused by hemolytic processes (ABO incompatibility or G6PD deficiency), bruising, or ingested maternal blood may be at higher risk. Additionally, infants with immaturities in conjugating bilirubin typically seen in Asian, late preterm, or infants with Gilbert disease may also develop exaggerated jaundice in the early days of life.

Prevention of breastfeeding jaundice is key. Encouraging exclusive and frequent breastfeeding at least 8 to 12 times per day, avoiding water or unneeded formula supplements, and teaching mother proper latch technique may help prevent poor intake, excessive weight loss and jaundice. Infants who have significant hyperbilirubinemia in the early days of life may at times need supplementation to assist in driving bilirubin levels down, but this is not routinely indicated. Misconceptions about breastfeeding jaundice have led physicians in the past to interrupt breastfeeding in this scenario. There is never a need to interrupt breastfeeding; an appropriate response is to optimize intake by improving milk transfer, having mother express milk to increase milk intake, or judicious use of pasteurized donor milk or formula supplements.

Infants who are readmitted to the hospital with excessive weight loss, dehydration, or hypernatremia often have hyperbilirubinemia as well. These infants require prompt treatment of their fluid and calorie deficits as well as management of hyperbilirubinemia. Assessment of milk transfer or consultation with a lactation specialist may help to preserve breastfeeding if an infant is readmitted to the hospital.

#### Breastmilk Jaundice

Breastmilk jaundice is thought to be a normal exaggeration of physiologic jaundice seen in human milk-fed infants. In these infants, serum unconjugated bilirubin will remain elevated, and a few infants may have elevated concentrations for as long as 6 to 12 weeks. In formula-fed infants, serum bilirubin declines, reaching values of less than 1.5 mg/dL by day 11 or 12 after birth. In contrast, by week 3, two-thirds of normal, thriving breastfed infants have serum bilirubin concentrations

above 1.5 mg/dL, and 30% will be clinically jaundiced. Authorities have suggested that the elevation in serum bilirubin may be protective against oxidative injury because it has been shown to be an effective antioxidant *in vitro*. Given that this elevation is a normal response to breastfeeding, other than jaundice, the infants seem healthy and are thriving. These infants exhibit no abnormal clinical signs suggesting hemolysis, infection, or metabolic disease. The etiology is unknown, but factors in human milk which increase the enterohepatic cycle of bilirubin or genetic variations which impair bilirubin hepatic conjugation, such as occurs in Gilbert disease, are hypothesized. Breastfeeding should be continued, and parents should be reassured.

The physician should ensure that no other causes of prolonged indirect hyperbilirubinemia (eg, galactosemia, hypothyroidism, urinary tract infection, pyloric stenosis, hereditary spherocytosis) are present. These causes may be identified on newborn screening, from the hospital records, or physical examination. Serum total and direct bilirubin and other indicated laboratory values should be measured if the clinical examination indicates an elevated bilirubin level or if jaundice persists for more than 3 weeks. The persistent rise in serum bilirubin or a total bilirubin greater than 20 mg/dL may necessitate phototherapy and consideration of interrupting breastfeeding for 24 to 48 hours. If breastfeeding is interrupted, the mother should be encouraged and helped to maintain her milk supply. The mother may be reluctant to resume breastfeeding because of the association between breastfeeding and jaundice. A positive attitude on the part of the health care professionals and assurance that this circumstance will not recur later may prevent termination of breastfeeding.

### Ankyloglossia

Ankyloglossia (tongue-tie) is the presence of a short or tight lingual frenulum that can restrict proper tongue extension and movement, hindering proper breastfeeding abilities in the infant. It is estimated that 2% to 5% of newborns have tongue-tie. In many, this is a normal variant of no consequence, but some infants demonstrate poor feeding and slow weight gain; the mother may suffer from severe nipple pain. Recent research suggests that frenotomy, when performed for clinically significant ankyloglossia, may lead to fewer problems breastfeeding and reduction in maternal pain.

## SUMMARY

Primary care physicians and other health care professionals should recommend human milk for almost all infants and should provide parents with complete, current information on the benefits and techniques of breastfeeding to ensure that their feeding decision is a fully informed one. Peripartum policies and practices that optimize breastfeeding implementation and maintenance should be encouraged. Healthy infants should be placed and remain in direct skin-to-skin contact with their mothers immediately after delivery until the first feeding is accomplished. All breastfeeding newborn infants should be examined by a pediatrician or other knowledgeable and experienced health care professional at 3 to 5 days of age.

## Chapter 89

# THE CIRCUMCISION DECISION

Andrew L. Freedman, MD

The choice of whether to have one's newborn son undergo a circumcision has for many new parents become one of the most difficult and anxiety-provoking decisions encountered in the newborn period. Although many parents approach this with relatively little reflection having had their minds made up for a long time, others agonize, often sensitive to the current debate in the larger culture. Although circumcision has ancient roots, dating back 6,000 years to Egypt, and remains the most common operation performed in males in the United States, we are currently witnessing a period of significant reevaluation, in part because of the development of an increasingly vocal opposition to the practice.

This sense of conflict is almost uniquely an American experience. In most of the world the primary indication for circumcision is religious tradition or local culture, but in the United States it is predominantly considered a medical procedure, divorced of religious significance, and greatly influenced by the

parents' beliefs regarding hygiene, health benefits, and potential risks. Although incompletely understood in contemporary American culture, clearly this decision has many influences beyond the medical, including religion, ethnicity, family tradition, paternal status, and aesthetics. Thus, those for whom circumcision is not seen primarily as a medical or public health issue may have no trouble deciding, whereas those who are trying to choose on a purely medical basis are increasingly confronted by a torrent of conflicting messages.

The proper role of the physician is likewise evolving. Increasingly, being the child's advocate means being a source of unbiased information that will help parents navigate this debate and make a multidimensional decision that is right for them. However, the physician may feel uncomfortable discussing the non-medical aspects or worry that their own beliefs may be biasing their discussion. To aid the physician as well as patients, representative professional organizations have developed guidelines for newborn circumcision. The most influential of these guidelines in the United States have been the ones developed by the American Academy of Pediatrics (AAP).

The AAP guidelines, first published in 1971, have undergone several revisions. They most recently underwent an extensive reevaluation and were published in 2012. The AAP guidelines are frequently misinterpreted as having a pro or con stance. The policy states that circumcision has benefits and risks, but overall the benefits outweigh the risks. However, the benefit is not great enough to recommend universal newborn circumcision. The policy does support access to the procedure for families desiring a circumcision. The policy also recommends that circumcision be performed by a trained provider, under hygienic conditions, and with the use of adequate pain management. Thus, the final decision is left in the hands of the well-informed parent.

The purpose of this chapter is not to support or condemn circumcision, nor to provide a comprehensive review of the vast circumcision literature, but rather to provide pediatricians with a brief summary of the most commonly discussed issues along with generally accepted data to allow them to be able to help inform parents. The chapter intends to support the use of the AAP guidelines. All physicians involved in newborn circumcision are strongly encouraged to read the revised guidelines and accompanying technical report (see AAP Policy at the end of this chapter).

## INCIDENCE OF CIRCUMCISION

The rate of newborn circumcision has been steadily falling over the past several decades since hitting its peak in 1965 with 85% of boys being circumcised. There remain significant regional variations as well as variations in access to circumcision through governmental insurance. Rates vary widely among different racial, ethnic, and religious groups. Although significant on the world scene, where 25% of the population is circumcised, in the United States, ritual religious circumcisions represent a tiny component of circumcisions performed.

The overall circumcision rate in the United States in 2006, based on the National Hospital Discharge Survey, was 56%. It was highest in the North Central region at 78%, and lowest in the West at 34%. Nationwide there has been a trend toward a declining incidence of newborn circumcision over the past decade. Review of the National Hospital Discharge Survey has shown a drop from 64.5% in 1979 to 58.3% in 2010. Findings were similar in 2 other national hospital databases. An unknown percentage of boys, however, will obtain their circumcisions outside of the birth hospital, such as in clinics or physician offices.

## ARGUMENTS THAT SUPPORT CIRCUMCISION

The medical portion of a parent's decision making should be based on a factual assessment of the risks and benefits of newborn circumcision. Most parents, however, will have made up their mind before any discussion with their physician. The most common reasons stated are that they believe it promotes better or easier genital hygiene, and the circumcision status of the father. Much of the hygiene concern derives from a lack of knowledge about how to care for the uncircumcised penis and concern about its difficulty. However, when pressed further, the medical benefits most frequently stated by parents are decreased risk for urinary tract infection (UTI) in the first year of life, decreased risk for acquiring a sexually transmitted infection (STI) including HIV, and a decreased risk for penile cancer.

### Hygiene

Parents often express fears about their own ability to care for the uncircumcised penis as well as fears that the child will be unwilling or unable to maintain adequate genital hygiene. Most of the time, they are unaware of what proper hygiene actually entails. Although there are data showing that uncircumcised men wash their penis less than circumcised men, and that many uncircumcised men fail to retract the foreskin during voiding or bathing, there are no good studies systematically evaluating genital hygiene practices in children.

Parents should be reassured that satisfactory hygiene of the uncircumcised penis can be easily achieved at all age levels with no more than simple daily washing with soap and water. There is now an easily available information fact sheet on proper hygiene practices produced by the AAP titled *Care of the Uncircumcised Penis* (see Tools for Practice).

### Urinary Tract Infection

There have been numerous studies evaluating the association between infant UTI and circumcision status. In general, these studies have shown a consistently increased risk for a UTI in boys with an intact prepuce. The reported relative risk varies along with the definition of a UTI, method of urine collection, sample size, and coexisting factors. However, there is a fairly consistent 4- to 10-times relative risk reduction associated with circumcision. The risk for UTI in an intact boy is

in the range of 7 to 14 per 1,000, whereas in circumcised boys, the range is 1 to 2 per 1,000. However, it is clear that the overall absolute risk (about 1%) is lower than the overall baseline risk of asymptomatic bacteriuria in infant boys.

One concern is the possible confounding influence of premature infants, who are much less likely to undergo circumcision but are more likely to have additional medical encounters and obtain more urine cultures. A further confounding issue is the finding of greater bacterial colonization of the urethra and peri-urethral glans in uncircumcised boys, increasing the risk for contaminated specimens when obtained by a bag method. Despite these concerns, there remains a consensus that circumcision has a beneficial effect in reducing the UTI risk in infants. After infancy, the risk for UTI in both circumcised and uncircumcised boys is significantly reduced.

### **Sexually Transmitted Infections (Excluding HIV)**

Numerous studies have evaluated the effect of circumcision on the risk for STI. A meta-analysis of the literature suggests that there is a protective effect of newborn circumcision against ulcerative STIs, most significantly syphilis. There is also a protective effect against chancroid and herpes, though to a lesser degree. However, several other studies have refuted this effect. Circumcision has been thought to have a protective effect against human papillomavirus (HPV) in males as well as in transmission to females, although this effect is much lower in relatively low-risk men with fewer female partners. There is no evidence of a protective effect against the nonulcerative STIs, particularly gonorrhea and chlamydia.

Thus, there is an overall risk reduction in acquisition of certain non-HIV STIs afforded by circumcision, particularly syphilis, chancroid, and HPV, but not in gonorrhea or chlamydia. It is important to stress to parents that this protection alone is insufficient to lessen the practice of effective safe-sex measures.

### **Human Immunodeficiency Virus (HIV)**

The most provocative new information in the circumcision debate is the protective effect of circumcision in preventing male HIV acquisition during high-risk heterosexual activity. Three large randomized controlled trials conducted in Africa demonstrated a 50% reduction in HIV acquisition. This follows many other studies that had previously suggested such an association. Further, there is a plausible biologic theory for the effect based on viral adherence to Langerhans cells in the mucosal aspect of the prepuce as well as greater likelihood of sexual trauma to the intact prepuce creating breaks in the skin barrier. Using current patterns of HIV acquisition and disease prevalence, the Centers for Disease Control and Prevention calculated that circumcision could provide a 15.7% lifetime risk reduction for men in the United States. The current predicted lifetime risk for HIV in US men is 1.87%. Circumcision has been shown to be a cost-effective strategy in the United States despite the fact that no benefit of circumcision has been shown in the men having sex with men

(MSM) population, which is still the primary source of HIV acquisition in the United States.

From a world public health perspective, this has been recognized as an important new tool in the fight against HIV, particularly in those regions with a high prevalence in the female population and poor adoption of safe-sex practices. Whether this is a significant enough benefit to warrant a more positive recommendation in the US population remains a subject of debate.

### **Penile Cancer**

Penile cancer is a rare tumor in the United States and has been becoming rarer, with a recent incidence of 0.58 per 100,000. Geographic variation in incidence has frequently been used to bolster the argument in favor of neonatal circumcision. Many areas with a high incidence of penile cancer, such as Brazil (3.4 per 100,000) and India (1.8 per 100,000), have a low incidence of circumcision compared with populations with a low incidence of cancer and a high rate of circumcision, such as Jews in Israel (0.1 per 100,000). However there are areas with a similarly low incidence of cancer and a low incidence of circumcision, such as Japan (0.3 per 100,000), Finland (0.5 per 100,000), and ethnic Chinese in Singapore (0.6 per 100,000). It is suspected that other aspects of public health such as the availability of clean water and better hygiene practices may play a more important role.

The presence of a foreskin is a risk factor for squamous cell carcinoma but not carcinoma in situ. The overall risk is 2.3 times higher in men with an intact foreskin. However, this is a weaker risk factor than smoking (4.5 times) or history of a penile injury or tear (4 to 5 times). Phimosis is the greatest risk factor (11–16 times), and it accounts for most of the risk caused by the presence of a foreskin. In fact, in uncircumcised men without a history of phimosis, the risk for penile cancer is actually reduced by 50%. This suggests that the means by which circumcision reduces penile cancer is preventing phimosis; a healthy foreskin can have a protective effect.

## **ARGUMENTS OPPOSING CIRCUMCISION**

The main arguments against circumcision include a discounting or disagreement with the medical benefits, surgical risks, effects on sexual functioning and satisfaction, and ethical considerations in altering the bodily integrity of an individual without his consent. It is important to be aware of these issues because parents may have these concerns but be reluctant to address them, thinking that physicians may have a pro-circumcision bias and not be open to these concerns.

### **Discounting Medical Benefits**

The circumcision literature is vast, and it is not hard to find studies that refute or minimize any of the suggested potential benefits. Studies vary greatly in design, populations, definitions, and interpretations. There are few studies that meet the most rigorous

standards, and there is always the potential for bias in interpretation or patient selection. The publication of several meta-analyses and reviews has helped to improve the discussion but there is still plenty of room for continued debate. Unfortunately, most of the battles among researchers have been in this arena, leaving the other areas of concern without sufficient study.

### Surgical Complications

The true incidence of complications after circumcision is unknown, in part because of differing opinions about what constitutes a complication and differing standards for determining when a complication has occurred. Adding to the confusion is the separation of acute complications such as bleeding or infection, which are uncommon, from late complications such as adhesions, meatal stenosis, and an unacceptable cosmetic outcome, which may be more common. Lastly, complications of circumcision in the non-newborn have received little attention.

Based on 2 very large hospital-based series, the risk for a significant acute newborn circumcision complication in the United States is very low, 0.2% or 1 out of 500 circumcisions. Bleeding was the most common complication (0.08%–0.18%), followed by infection (0.06%) and penile injury (0.04%). However, in a smaller series using hand-reviewed medical records, complications were found to be much more common at 3.1%, with bleeding occurring in 2.1%, although most of these were mild in nature and did not require operative intervention.

Late complications of newborn circumcision include excessive residual skin (incomplete circumcision), excessive skin removal, adhesions (natural and vascularized skin bridges), meatal stenosis, phimosis (trapped penis) and epithelial inclusion cysts. Late complications in 1 outpatient-based study were found to include adhesions (25.6%), redundant residual prepuce (20.1%), balanitis (15.5%), skin bridge (4.1%), and meatal stenosis (7%). Although the true incidence of these late complications is not well established because there are few studies of the US experience, their incidence is clearly not trivial.

Most severe or even catastrophic injuries are of such a rare nature as to be reported as case reports without a clear sense of their overall incidence. Significant reported complications include glans or penile amputation, herpes transmission, methicillin-resistant *Staphylococcus aureus* (MRSA) infection, urethral cutaneous fistula, glans ischemia, and death.

### Sexual Effects

A frequent concern among those opposed to circumcision is a perception that there is decreased penile sensitivity. There are few methodologically rigorous studies, which in general do not support any significant loss of sensation or decreased sexual satisfaction. There have been reports of lengthened ejaculatory latency times, but it is unclear whether this leads to an increase or decrease in satisfaction. In an African study of female partner satisfaction, most subjects reported increased satisfaction after circumcision of their adult

male partner. The research in this area remains limited and often contains significant concerns of bias.

### Medical Ethics

One of the most challenging areas is that of the ethics of altering the child's bodily integrity without his consent. Although parents are generally asked to decide the medical course for their children, circumcision is somewhat unique because it is nontherapeutic at the time of its performance and some of the benefits being considered are nonmedical, such as cultural, religious, and aesthetic considerations. Although one can suggest that there may be a prophylactic effect for certain medical conditions, these conditions are generally uncommon and are not present at the time, and it is certainly not clear that any individual newborn is at an elevated risk.

Therefore, in the absence of a clear metric in which to weigh the risks and benefits, it is thought to be most ethical for the parents to determine what is in the best interest of the child. Furthermore, within the pluralistic framework of American society, parents are afforded wide latitude in determining what is appropriate for their child, and thus it is considered legitimate for them to take into account their cultural, religious, and ethnic traditions along with the medical information in making their decision.

Physicians have a moral obligation to avoid any coercion, provide unbiased and complete information, and do everything in their power to reduce the risk or suffering associated with the procedure, such as providing adequate pain management and having the procedure performed by well-trained personnel.

As with many ethical questions, this stance is not universally accepted, but at present it is representative of the organized medical community in the United States.

### THE CIRCUMCISION PROCEDURE

Circumcision in the newborn period should be performed only when the infant is stable and healthy and has urinated. There are 3 devices in common use for newborn circumcision: the Gomco clamp, the Mogen clamp, and the Plastibell. Success and complication rates are similar among the techniques. Contraindications for circumcision include hypospadias, congenital buried penis or other anatomic anomalies of the penis, neonatal illness, and bleeding disorders or a family history of bleeding disorders. After the first month of life, these techniques carry a greater risk. Non-newborn circumcision involves a more formal procedure and is typically done under general anesthesia.

All circumcision procedures should be preformed with adequate pain control. There is no longer any question that the newborns experience pain with circumcision. Pain control measures, including sucrose nipple, analgesics, topical anesthetic creams, dorsal penile nerve block, and subcutaneous ring block, have the ability to significantly decrease the pain associated with the procedure and can be safely used in combination. The most effective measures are the blocks—dorsal penile nerve block and ring block. They should be performed with 1% lidocaine in a buffered solution. The most common complications include

bruising or hematoma, which rarely require any additional treatment. Rare events include intravascular injection or allergic reaction. The topical lidocaine creams are less effective and need to be placed 45 to 60 minutes in advance of the procedure. There is some evidence that circumcision in the first week of life is better tolerated than later in the newborn period. Gentle restraint, especially with upper extremity swaddling, rather than 4-point restraint on a rigid board, is believed to be less stressful for the child.

## CONCLUSION

Newborn circumcision can no longer be considered a routine rite of passage for American boys. While providing some measurable benefits, primarily a decreased risk for HIV infection and infant UTI, it is not without a small but definable surgical risk. The benefits may be enough to justify its performance for those who desire it but likewise are not sufficient to recommend universal application. Because circumcision finds itself somewhere between recommendation and condemnation, ethically it falls to the parent to decide what is in the best interest of the child. The family is best aided by a knowledgeable physician who is able to provide unbiased information, sensitivity to the nonmedical dimensions, and assurance that the procedure is performed in a safe, hygienic, and compassionate manner.

## Chapter 90

# CARE OF THE LATE PRETERM INFANT

Sheri L. Nemerofsky, MD; Viral A. Dave, MD;  
Deborah E. Campbell, MD

## INTRODUCTION

Prematurity continues to be an issue of major concern. In the United States alone, preterm births account for more than 500,000 infants born each year. From 1990 to 2006, the rate of preterm birth rose dramatically to 12.8%. Fortunately, it decreased consecutively over the following 5 years to 11.72% in 2011 (Figure 90-1). Most premature infants, approximately 70%, are born between 34 and 36 weeks' (34<sup>0</sup>/<sub>7</sub>–34<sup>6</sup>/<sub>7</sub>) gestation and are considered late preterm (LPT).

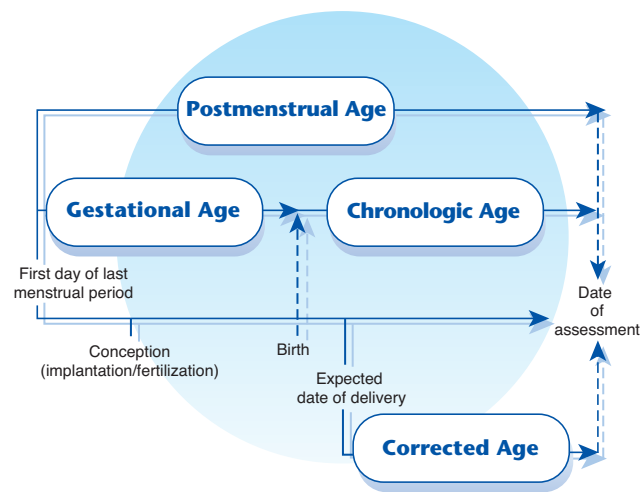

Worldwide, LPT birth rates are similar and make up the vast majority of preterm births. The term *prematurity* is used to describe any infant born before 37 weeks' gestation. Preterm babies are grouped into subcategories based on their degree of prematurity. Previous convention described infants born at 32 to 34 weeks' gestation as moderately preterm and at 35 to 37 weeks' gestation as near term. Recognition of the increased vulnerability associated with birth between 34 and 36 weeks' gestation led to the 2005 Workshop on Optimizing Care and Long-Term Outcome of Near-Term Pregnancy and Near-Term Newborn Infants, which refined the definition of the LPT infant to mean delivery from 34<sup>0</sup>/<sub>7</sub> to 36<sup>6</sup>/<sub>7</sub> weeks' gestation (239–259 days) (Figure 90-2).

The rise in preterm birth rates is a result of many variables. In the United States, advanced maternal age is defined as a woman more than 35 years old. The number of women in this demographic delivering babies has steadily increased over the years. These women have an increased risk for having an LPT infant (adjusted odds ratio, 1.23), and in a recent report, almost 19% of women older than 44 years delivered infants prematurely (Figure 90-3).

Multiple gestations are another significant contributor to the increased LPT birth rate. The incidence of multiple births has increased significantly over the past 40 years in conjunction with advances in and greater access to assisted reproductive technologies.

**Figure 90-1** Incidence of preterm birth rate.

**Figure 90-2** Age terminology during perinatal period.

**Figure 90-3** Late preterm birth rates by age of mother: United States, 1990, 2000, and 2006. (From Menacker F, Hamilton BE. Recent trends in cesarean delivery in the United States. NCHS Data Brief. 2010;Mar[35]:1-8)

**Figure 90-4** Late preterm births per 100 total births.

The rate of twinning increased 76% from 1980 to 2009. Although higher order multiples (3 or more) have decreased during the past 3 years because of changes in assisted reproductive practices, twins continue to account for 3% of all births in the United States. Approximately 50% of twins and 44% of triplets are born LPT (Figure 90-4).

### MORBIDITY AND MORTALITY

As a group, LPT infants experience increased morbidity and a higher incidence of mortality than their full-term counterparts. Late preterm infants represent 33% of total neonatal intensive care unit (NICU) admissions. With decreasing gestational maturity, the percentage of preterm infants requiring intensive care increases. Recent studies have shown significant heterogeneity, with reports of 33% to 100% of infants born at 34 weeks, 15% to 43% of infants born at 35 weeks, and 8% to 21% of babies born at 36 weeks requiring NICU admission.

Reasons that LPT infants require NICU admission include difficulty with thermoregulation and control of cardiorespiratory function (apnea, bradycardia, and hypoxic episodes), problems with oral feeding, hypoglycemia, hyperbilirubinemia, respiratory distress, and suspected sepsis.

The LPT infant also has an increased risk for short-term and long-term complications. Approximately 7% to 9% of newborns born at 34 to 36 weeks' gestation require rehospitalization within 14 days of nursery discharge. A significant portion of LPT infants continue to have ongoing health and developmental issues throughout childhood that require rehospitalization, extensive medical visits, and an increased need for social and educational support.

The mortality rate of LPT infants is also significantly higher than that of full-term babies. Infant mortality classified by the postnatal age categories of early neonatal (0–6 days), late neonatal (7–27 days), and post-neonatal (28–364 days) are notable for mortality rates that are 6, 3, and 2 times higher, respectively, than term infants. With each week of gestation, the risk for death decreases significantly. In 2009, the mortality rate for LPT infants was between 2.8 and 7.1 per 1,000 (Table 90-1).

**Table 90-1**

**Neonatal Mortality  
per 1,000 Births**

WEEKS OF GESTATION	RATE	RR (95% CI)
34	7.1	9.5 (8.4–10.8)
35	4.8	6.4 (5.6–7.2)
36	2.8	3.7 (3.3–4.2)

### HEALTH CARE UTILIZATION: ECONOMIC IMPACT

Despite the increased risk for morbidity and mortality, many LPT infants are routinely cared for in regular newborn or well-baby nurseries rather than special (level II) or neonatal intensive (level III) care units and are often discharged home at 2 to 3 days of age. The birth weights of these infants are typically more than 2,500 g, and they may seem physically more mature. This leads to many LPT infants being treated the same as the developmentally more mature full-term infants. The misconception that LPT infants have similar risks as term infants is common. However, it is not uncommon for the initial birth hospitalization stay to be significantly longer than for full-term infants, 2.6 days versus 1.96 days. Irrespective of the initial birth hospitalization, these infants are more likely to be readmitted to the hospital. Causes include dehydration, excessive weight loss, feeding problems, jaundice, and suspected sepsis in the first weeks of life.

According to the revised policy statement on neonatal care from the American Academy of Pediatrics (AAP) Committee on Fetus and Newborn, level I nurseries should provide care for infants born at 35 weeks' gestation or later who remain physiologically stable and stabilize those born earlier than 35 weeks until transfer to a higher level facility is available. Within institutions where regionalized perinatal health systems are in place, neonatal transfer policies determine where care for these babies occurs.

Costs for prolonged birth hospitalizations, rehospitalizations, and associated medical care of LPT infants are greater than for full-term newborns. The higher initial birth hospitalization costs are a common occurrence worldwide and range from \$5,000 to \$15,000. This cost is associated with a number of factors, including equipment for care and treatment, medications, and staffing.

The costs continue to rise well beyond the initial birth hospitalization. On average, LPT infant medical care costs in the first year are 3-fold higher than those for full-term infants. The hospital costs in the first year of life for LPT infants were 3.21 times more likely to be above \$25,000. In addition, outpatient costs for the first year were \$6,981 for LPT infants compared with \$2,158 for full-term babies. The mean total cost for LPT infants during the first 2 years of life continues to exceed the cost for full-term infants. Emergency department (ED) visits, outpatient physician office visits, and hospitalizations are much more frequent among LPT infants.

## HEALTH ISSUES INFLUENCING NURSERY CARE OF THE LATE PRETERM NEWBORN

Transitional issues such as transient tachypnea of the newborn, cold stress caused by hypothermia, and hypoglycemia may be seen during the early hours after birth.

### Cold Stress and Hypothermia

Preterm newborns have an impaired ability to prevent heat loss and increase their body heat production in response to low environmental temperatures. The risk for cold stress is greatest during the immediate transitional period after delivery and is caused by the preterm newborn's immature skin, the decreased amount of brown fat, the high ratio of surface area to birth weight, and the environmental conditions in the delivery room (large temperature gradients between the newborn's body temperature and the ambient temperature of the delivery room, airflow through the room, and contact with cold surfaces that lead to significant evaporative, radiant, convective, and conductive heat losses). Wide variations in delivery room temperatures have been reported to have a significant effect on a newborn's temperature. Approximately 50% of newborns experience some degree of cold stress after birth.

Oxidation of fatty acids is the predominant method of nonshivering heat production in newborns regardless of gestational age or birth weight. Brown fat, the major store of fatty acids in neonates, is located around the mediastinal structures, kidneys, scapulae, axillae, and nape of the neck. Cold exposure activates the sympathetic nervous system, releasing norepinephrine. In turn, norepinephrine stimulates the hydrolysis or breakdown of brown fat, with resultant heat production. LPT infants have decreased brown fat compared with full-term infants. Consequently, they are more prone to develop cold stress and hypothermia. Normal core body temperature for a neonate is 36.5°C to 37.4°C (97.7°F to 99.3°F). Clinical manifestations of cold stress are nonspecific. Common findings include hypoglycemia, tachypnea, peripheral vasoconstriction, pallor, mottling caused by vasomotor instability, and metabolic acidosis. Therefore, maintaining thermoregulation, keeping the newborn warm, and minimizing heat loss and energy expenditure are important components of the preterm newborn's initial care after birth.

Strategies to minimize heat loss include the following:

- Maintain the delivery room and all other patient care rooms at a temperature of 24°C ± 2°C (75°F ± 3°F). (The World Health Organization recommends 25°C or greater.)
- Prewarm the radiant warmer.
- Initiate skin-to-skin contact with the mother to facilitate temperature regulation of the newborn.
- Rapidly dry the newborn after delivery.
- Cover the newborn's head with a hat to reduce heat loss.
- Place the newborn in an isolette when not in skin-to-skin contact with the mother if the newborn is exhibiting difficulty maintaining body temperature.

### Respiratory Disorders and Respiratory Distress

Acute respiratory distress is a common condition experienced by the LPT newborn. Neonates born between 34 and 36 weeks' gestation who exhibit respiratory distress after delivery are at increased risk for associated morbidities. Late preterm newborns exhibit higher rates of transient tachypnea of the newborn (TTN), respiratory distress syndrome (RDS), persistent pulmonary hypertension, and respiratory failure. TTN and RDS are both common in the late preterm newborn and are related to delayed clearance of lung fluid, surfactant deficiency, or both. One-third of LPT newborns will exhibit respiratory difficulties. More than 8% of LPT infants experience severe respiratory disorders, requiring nasal cannula, continuous positive airway pressure (CPAP), or mechanical ventilation.

In utero, alveoli are filled with fluid that must clear during the initial transitional period for effective ventilation to be established. In addition, pulmonary blood flow to the lungs increases to ensure effective pulmonary perfusion and adequate matching of perfusion and ventilation. A significant part of this process includes fluid clearance through transepithelial sodium absorption that occurs during the process of labor and vaginal delivery. Liquid is also driven through the pulmonary epithelium into the vasculature. Maturation and recruitment of epithelial sodium channels occur during the last few weeks of pregnancy in response to endogenous steroid and catecholamine surges that are triggered by the onset of labor. Neonatal transition may be more difficult when the infant is born by cesarean delivery without onset of labor. Impaired function or inactivity of the sodium channels contributes to TTN and RDS. Although administering antenatal corticosteroids results in a significant reduction in mortality and morbidity caused by RDS in premature infants, the American College of Obstetricians and Gynecologists does not recommend routine antenatal steroid use after 34 weeks' gestation.

Strategies to minimize the risk for respiratory morbidity include the following:

- Personnel skilled in the assessment, resuscitation, and stabilization present in the delivery room.
- The use of CPAP and initiation of resuscitation in the delivery room as needed
- Attention paid to maintaining thermoneutrality and glucose homeostasis to avoid additional morbidity that may prolong the newborn's physiologic transition and worsen respiratory symptoms.

### Risk for Infection

One major cause of preterm delivery is infection. Late preterm infants are more susceptible to infection, congenital or acquired, because of immaturity of their immune system. (See Chapter 102, The Newborn at Risk for Infection.) As a group, LPT infants are nearly 4 times more likely to be evaluated for suspected sepsis than the full-term neonate and are more likely to be treated with a 7-day course of antibiotics. In addition, clinical signs during the transitional period may mimic

early signs of systemic infections. These include respiratory distress, temperature instability, low tone, poor feeding, and evidence of hemodynamic instability.

Late preterm infants often experience increased respiratory morbidity during infancy, including RSV infection, wheezing, the need for treatment with inhaled corticosteroids, and greater risk for developing asthma. RSV infection in this group of infants leads to significantly more emergency department visits (3.6- to 6.2-fold higher than for full-term infants) and outpatient physician office visits. Respiratory issues are the leading cause of outpatient visits for LPT infants.

Strategies to minimize morbidity related to infection risks include the following:

- Review the maternal medical history including onset of labor, length of rupture of membranes, and timing of antibiotics. Monitor and thoroughly assess the infant for signs of infection and initiate therapy as appropriate.
- Follow guidelines based on the Centers for Disease Control and Prevention (CDC) Group B Streptococcal Disease Revised Guidelines.
- Encourage early and exclusive breastfeeding, by either direct breastfeeding or the provision of expressed breast milk.
- Consider palivizumab administration for infants born before 35 weeks' gestation who are less than 90 days of age at the start of the RSV season and who have 1 or more additional risk factors (infant is in daycare or has school-aged siblings younger than 5 years).
- Discuss pollutants and adverse effects of second-hand smoke and other environmental exposures at each office visit.

### Hepatitis B Vaccination

According to the 2012 CDC Advisory Committee on Immunization Practices recommendations, all infants born to hepatitis B surface antigen-positive mothers should receive hepatitis B (HBV) vaccine and hepatitis B immune globulin (HBIG) within 12 hours of birth. If the mother is negative, then the infant should receive HBV vaccine before discharge. In neonates whose birth weight is less than 2,000 g, the initial vaccine dose confers lower immunogenicity than in infants born at term. Therefore, infants weighing less than 2,000 g should receive a total of 4 doses of HBV vaccine (birth and 1-2, 3-4, and 6 months). In cases of unknown maternal status at delivery, all infants should receive HBV vaccine within 12 hours after birth. If the infant weighs less than 2,000 g, then the HBIG should also be administered; otherwise, it can be held for 1 week until maternal status is confirmed. The AAP recommends that all neonates should receive the first dose of vaccine in the hospital.

### Hypoglycemia

Glucose is a primary energy source for the newborn infant. Gestational age, hypothermia, hypoxia, maternal diabetes, maternal glucose infusion in labor, intrauterine growth restriction, small for gestational age, and sepsis are all factors that may contribute to the incidence of hypoglycemia. Hypoglycemia occurs more often in premature infants as a result of decreased hepatic

glycogen stores, decreased gluconeogenesis, and ketogenesis. Feeding may also be less efficient in some LPT infants because of easy fatigability and immature feeding skills. Limited enteral intake further complicates the newborn's initial transition, predisposing the LPT newborn to hypoglycemia.

Hypoglycemia has been reported to occur in 25% of LPT infants (see Chapter 105, Transient Metabolic Disturbances in the Newborn). An important element of care in prevention of hypoglycemia in the LPT newborn is appropriate risk assessment with glucose screening. The AAP Committee on Fetus and Newborn released recommendations for glucose screening of at-risk newborns, including LPT infants. In summary, a blood glucose level greater than 40 mg/dL (2.2 mmol/L) is acceptable in the first 4 hours of life. After 4 hours of age, the infant should maintain a blood glucose level above 45 mg/dL (2.5 mmol/L). Late preterm infants are at greatest risk for developing hypoglycemia during the first 12 hours of life, although they should have preprandial glucose monitoring for at least the first 24 hours of life because they remain more vulnerable to low glucose concentrations, particularly if regular feedings are not well established.

Strategies to assess the risk for hypoglycemia include the following:

- Assess all LPT infants for hypoglycemia.
- Initiate early breastfeeding or formula feedings within 60 minutes of birth.
- Monitor glucose 30 minutes after the first feeding.
- Maintain blood sugar higher than 40 mg/dL in the first 4 hours of life and higher than 45 mg/dL thereafter.
- Continue to monitor blood sugar every 3 hours before feeds until 3 stable blood sugars are recorded.

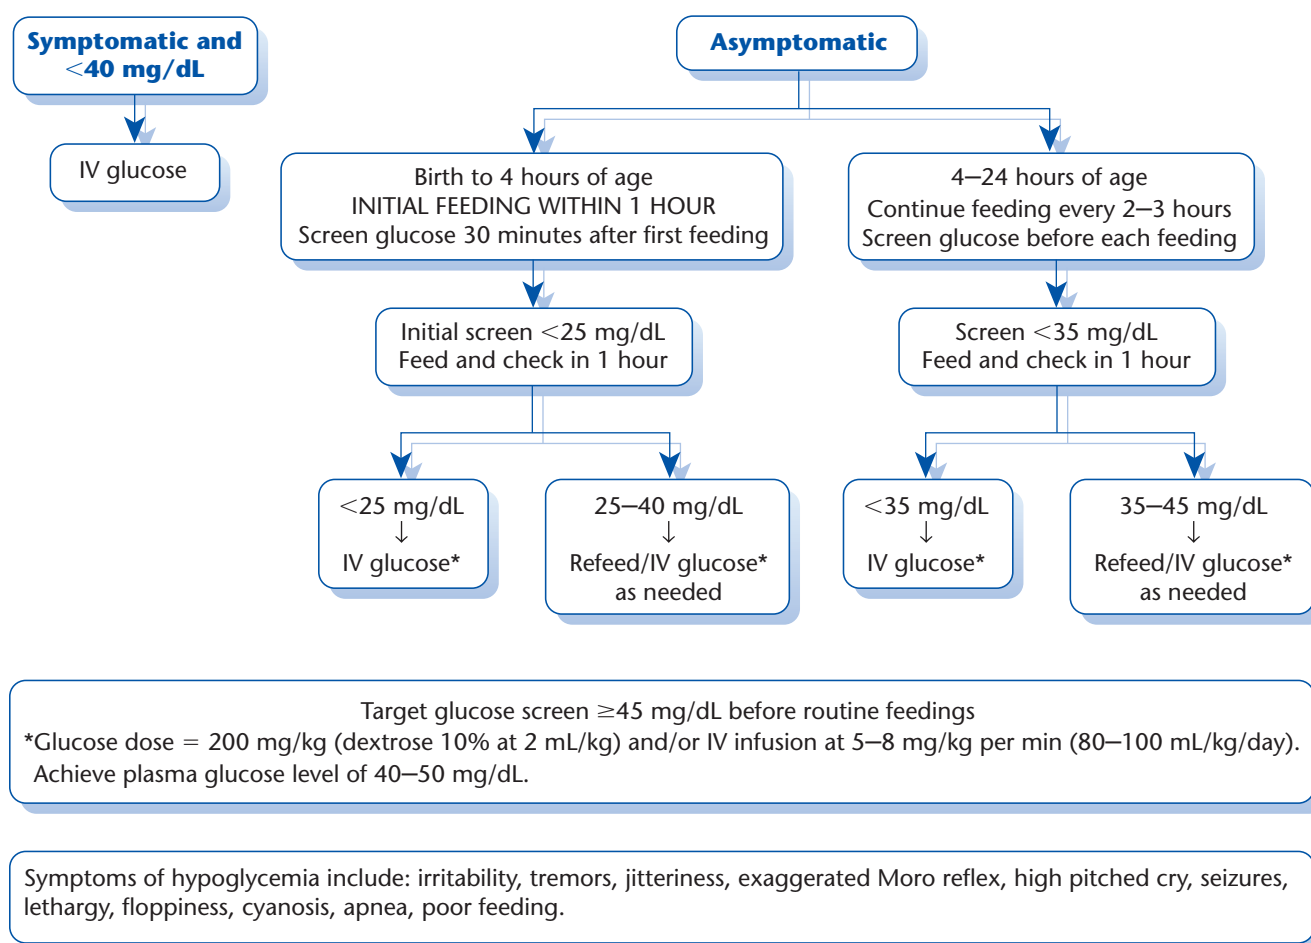

The AAP Committee on Fetus and Newborn offers guidelines for the management of hypoglycemia (Figure 90-5).

### Feeding Issues

#### Feeding Tolerance

Maturation of the gastrointestinal tract is important not only for digestion and absorption but also for endocrine and exocrine function. Significant increases in the intestinal length and surface area, including villus and microvillus growth, occur during the last trimester. Most LPT newborns are able to tolerate human milk and infant formula without difficulty despite these developmental differences. Although LPT infants have low gastric acid secretion and limited pancreatic enzyme activity, they are able to digest whole-protein formulas. Despite decreased bile acid secretion, enterohepatic circulation, and lower lactase activity, LPT infants are generally able to digest fats and carbohydrates. Premature infants often have intestinal motor function immaturity that contributes to feeding intolerance. Intestinal dysmotility is typically present up to 34 weeks' gestation but may persist. Some infants may require a longer interval between feedings because of a delay in motility and gastric emptying.

An important point to consider is the adequacy of the infant's intake and growth pattern. Many LPT infants are not able to demonstrate clear feeding cues, and some may lack suck-and-swallow coordination

**Figure 90-5** Screening and management of postnatal glucose homeostasis in infants who are small for gestational age, infants who are large for gestational age, infants who were born to mothers who have diabetes, and late preterm infants.

skills. The strength and efficiency of the suck patterns and suck, swallow, and breathing coordination may further impede successful oral feeding and contribute to excessive weight loss or poor weight gain. Other feeding problems include latching, feeding fatigue with progressive feeding disorganization, and loss of suction during suckling, in some instances causing respiratory compromise (choking, coughing, duskiness) (Figure 90-6).

Feeding issues continue after nursery discharge for many preterm infants. The most common problems, which sometimes lead to rehospitalization, are decreased appetite, oromotor dysfunction, and avoidant feeding behavior. Most feeding recommendations are geared toward very preterm infant; little research has been conducted specifically for the LPT infant.

It is important that nutritional intake and feeding plans are discussed during each office visit until effective feeding patterns and adequate weight gain are established. Although LPT infants may lose up to 12% of their birth weight during the first week of life, weight loss of more than 3% in the first 24 hours of life or greater than 7% at 48 hours of age is of concern.

A careful assessment of the infant's state regulation, hydration status, glucose levels, feeding patterns, and feeding skills is necessary, as is review of types of feeding (breastfeeding and/or bottle feeding). Assessment of maternal lactation during this time is also important for the breastfeeding LPT infant.

### Breastfeeding

Human milk provides substantial benefits to infants' health. Human milk feeding is associated with reduced infectious and inflammatory disease, metabolic disease, and obesity, as well as enhanced neurodevelopmental outcome and healthy postnatal growth patterns. The AAP recommends exclusive breastfeeding for 6 months, followed by breastfeeding in combination with the introduction of complementary foods until at least 12 months of age, and continuation of breastfeeding for as long as mutually desired by mother and baby. Initiation of breastfeeding in LPT infants occurs in 59% to 75% of newborns in the United States, and it seems that NICU admission may have a positive effect on continuation and length of breastfeeding among all infants.

**Figure 90-6** Incidence of feeding problems affecting late preterm infants, by gestational age.

Strategies to support optimal nutrition for the LPT infant include the following:

- Human milk should be the first choice.
- Mothers can also combine hand expression of breast milk with the use of an electric breast pump because this technique has been shown to increase milk volumes more rapidly than breast pump use alone.
- Infants should be put to breast within the first 30 to 60 minutes after delivery.
- Lactation consultation should be offered within 24 hours of birth.
- Direct observation and documentation should be undertaken every 12 hours while in the hospital.
- Infants should be breastfed 8 to 10 times in a 24-hour period.
- Expressed breast milk can be stored and offered to the infant following each nursing attempt until lactation is established and the infant is feeding effectively at the breast.
  - Day 1 (Birth–24 hours of age): offer 5 to 10 mL at each feeding
  - Day 2 (25–48 hours of age): offer 10 to 20 mL at each feeding
  - Day 3 (49–72 hours of age): offer 20 to 30 mL at each feeding
- Mothers should maintain a feeding log with the frequency and duration of nursing episodes and the quantity of expressed breast milk or formula fed.

The LPT infant who loses more than 7% of birth weight during the first 2 days of life is at higher risk for excessive weight loss, dehydration, severe hyperbilirubinemia, and rehospitalization within the first 2 weeks of life. The physician will need to decide in consultation with the family whether the infant can be discharged home with close primary care follow-up or requires continued hospitalization until feeding improves and weight stabilizes.

- If the infant is discharged home, the infant should be reevaluated within 24 to 48 hours.
- A postdischarge lactation consultation may be arranged if feasible (LaLeche League and WIC are

valuable community resources that offer lactation support and peer counseling; some hospitals offer lactation support clinics).

- Mothers should continue to keep a log of the infant's feedings, any supplementation given, and the infant's elimination pattern.
- Mothers should have a clear feeding plan for their LPT infant at discharge irrespective of whether the infant is breast or formula feeding.
- Although most formula-fed LPT infants will be fed a 20-cal/oz term infant formula, those who are small for gestational age or who exhibit excessive weight loss and/or poor weight gain may require higher-calorie infant formula.
  - Higher-calorie formula can be transitioned to standard 20-cal/oz infant formula when the infant is demonstrating good weight gain, 30 to 40 g/day, and growth and is above the 10% for postmenstrual age on the CDC or World Health Organization infant growth curves.

The following are indications for concern:

- Feeding duration greater than 30 minutes or fewer than 6 feedings per day
- Fussiness, distress, or difficulty breathing during feedings
- Difficulty waking the infant for feeding or difficulty completing a full feeding
- Infant refusal of feedings or gagging, coughing, cyanosis, or frequent choking while feeding

Soy formulas are not recommended for preterm infants born at less than 1,800 g.

### Hyperbilirubinemia

Prematurity is one of the main risk factors for the development of significant hyperbilirubinemia and is associated with an increased risk for kernicterus. Jaundice in the LPT infant often has a more severe and protracted course than in term infants. Bilirubin levels typically peak between 5 and 7 days in the premature infant and decline slowly thereafter. If bilirubin levels reach critically high values, kernicterus may occur.

In LPT infants, the progression to kernicterus can be insidious. Kernicterus is a preventable brain injury; failure to diagnose and properly treat the LPT infant with significant hyperbilirubinemia may place the physician at medical-legal risk. Pediatricians should consider testing the cord blood of any infant born to a woman who had no prenatal blood grouping or who is antibody positive or Rh negative. It is recommended that all infants be screened for jaundice before initial hospital discharge. The 2004 AAP Clinical Practice Guideline and the National Institute for Health and Care Excellence guidelines are very useful for infants born at 35 weeks' gestation or later. However, one must be careful using this guideline for all LPT infants. (See Table 90-2.) Consensus guidelines were published in 2012 for the clinical evaluation and management of hyperbilirubinemia in preterm infants born before 35 weeks' gestation (see Chapter 99, Neonatal Jaundice).

Strategies to consider for management of hyperbilirubinemia in the LPT infant include the following:

- Obtain transcutaneous or total serum bilirubin before discharge.
- Follow up within 1 to 2 days of discharge and repeat transcutaneous or total serum bilirubin levels as needed.

### Brain Maturation and Neurodevelopment

Most brain growth occurs during the last half of gestation, with 35% of the brain's weight accrued in the last 6 weeks of gestation. Although neuronal proliferation and migration are considered complete by 24 weeks, the brain's gyri and sulci are not fully developed until about 40 weeks' gestation. In addition, a 4-fold (50%) increase in cortical brain volume occurs during the third trimester. Synaptogenesis, dendritic branching, and maturation of oligodendrocytes also continue through the last weeks of gestation. These processes are extremely sensitive and susceptible to hypoxic-ischemic and free radical injury, particularly the oligodendrocytes.

Brainstem function and autonomic and respiratory control are also immature, contributing to periodic breathing, apnea, desaturations, and bradycardia in the preterm infant. As previously described, inefficient feeding skills in conjunction with poor coordination of suck, swallow, and breathing and episodic gastroesophageal reflux precipitate these physiologic responses. The incidence of sudden infant death syndrome in preterm infants between 33 and 36 weeks' gestation is nearly twice as high as that of term infants. For infants between 34 and 37 weeks' gestation, the relative risk for experiencing an episode of prolonged apnea or bradycardia requiring intervention (apparent life-threatening event) is 3 times greater than for the term infant. The Collaborative Home Infant Monitoring Evaluation (CHIME) study found that 30% of the study infants who experienced an apparent life-threatening event were less than 38 weeks' gestation at birth. The younger the preterm infant, the earlier symptoms were exhibited. (See also Chapter 217, Apparent Life-Threatening Events.) Electroencephalogram/sleep patterns are also very different in LPT infants compared with full-term infants.

Some hospital practices and primary care physicians may consider home monitoring for the LPT infant. However, no data are available that support the routine use of home monitoring for this group of infants. Considerations regarding these care recommendations should be based on the infant's clinical and family history. Parents of LPT infants should be counseled about infant safety and safe sleep practices, including that preterm infants should be placed supine for sleep and that all other recommendations regarding safe sleep practices for infants are applicable to their preterm infant.

### Neurodevelopmental Outcomes

There have been numerous studies published in the past 5 years describing neurodevelopmental outcomes for LPT infants. Although the incidence of neurodevelopmental delays and impairment among LPT infants is

**Table 90-2**

**Total Serum Bilirubin Levels at Which Interventions Are Recommended for Late Preterm Infants**

RISK FOR BIND (AAP GUIDELINES <sup>a</sup> )	TSB THRESHOLD AT AGE 48 hr (mg/dL)		TSB THRESHOLD AT AGE ≥96 hr (mg/dL)	
	PHOTOTHERAPY	EXCHANGE	PHOTOTHERAPY	EXCHANGE
High (presence of any BIND risk factors <sup>b</sup> and 35 <sup>0</sup> / <sub>7</sub> to 37 <sup>6</sup> / <sub>7</sub> wk)	11	18	15	19
Moderate (35 <sup>0</sup> / <sub>7</sub> to 37 <sup>6</sup> / <sub>7</sub> wk with no BIND risk)	13	20	18	22.5
Low (term infant with no BIND risk)	15	22	21	25

AAP, American Academy of Pediatrics; BIND, bilirubin-induced neurologic dysfunction; TSB, total serum bilirubin.

<sup>a</sup>American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Clinical practice guidelines. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114(1):297–316

<sup>b</sup>BIND risk factors: isoimmune hemolytic anemia; glucose-6-phosphate dehydrogenase deficiency; significant lethargy, sepsis, acidosis, asphyxia, temperature instability, and serum albumin level.

not as high as in the very preterm infant, it remains a significant problem. As a group, LPT infants have more early intervention needs than full-term infants, yet many of these vulnerable infants do not receive developmental services because of delays in or missed opportunities for diagnosis. LPT infants constitute a group of infants requiring developmental surveillance and periodic developmental screening. Although LPT infants are not routinely referred to early intervention, 30% of LPT infants admitted to the NICU qualify and receive services by 1 year of age.

Although about half of all LPT infants require NICU admission at birth, developmental assessment at 3 years of age is the same as in those who did not need a NICU admission. The studies seem to be consistent showing the increased risk for neurodevelopmental morbidities into school age. Emotional and behavioral issues are significant and challenging for families of LPT infants. At the end of their first year of school, by age 5 years, LPT children had lower personal, social, and emotional developmental scores. Kindergarten is a crucial age for children because it often sets them on their scholastic path. In Florida, risk for suspension from kindergarten is 19% higher for children born LPT. As the LPT population ages, the deficits among this group seem to persist. In New York City, by the third grade 25% of LPT children have educational disabilities requiring special education services. Realizing that these infants continue to have difficulties throughout childhood, it is worthwhile to consider early surveillance and periodic screening for neurodevelopmental and behavioral difficulties and delays.

### Additional Routine Care Issues

#### Car Seat Safety

According to US Federal Motor Vehicle Safety policy, the maximum weight acceptable for use of an infant car seat is 50 lb; however, no minimum weight is specified. Preterm infants may have episodes of oxygen desaturation when placed in a standard upright infant car seat. It is now recommended that all infants younger than 37 weeks' gestation (including those cared for in a regular newborn nursery) have an infant car seat challenge test before hospital discharge. This usually entails the infant being placed on a pulse oximetry monitor for 60 to 120 minutes to evaluate the infant for apnea, desaturations, or bradycardia while in the car seat. This will assist parents with proper positioning of the baby and determine the length of time the infant should remain in a car or infant seat without repositioning or removal from the seat in order to reduce the risk for cardiorespiratory compromise. Rolled towels or blankets may be placed on both sides of the infant for head and neck support. It should be explained to parents that the time the infant spends in an infant (car) seat should be kept to a minimum. Infants who exhibit apnea, bradycardia, or desaturations while upright are advised to travel in a supine position in a car bed. It is thought that infants transported in car beds are less likely to exhibit desaturations. It is prudent to educate parents about proper car seat positioning and limiting the time spent in a car or infant seat to less than

60 minutes when possible. At a minimum, parents and other caregivers should be instructed to check the infant and reposition if travel is in process or remove the baby from the car or infant seat when travel is complete.

Babies discharged with home monitoring should also be monitored during travel. For the infant discharged on oxygen, proper storage of the oxygen tank and apnea monitor during travel includes placing the equipment below the infant seat or on the vehicle floor for safety purposes. As of 2013, the AAP recommends that all infants and toddlers remain rear-facing until they are 2 years old.

#### Specific Newborn Screening Tests in the Hospital

All newborn blood spot screening procedures should be conducted by 3 days of life. Newborn hearing screens using either automated auditory brainstem response or otoacoustic emission testing devices should be completed before discharge from the hospital. If the infant requires more than 5 days of hospital care or received aminoglycosides, it is recommended that the infant undergo automated auditory brainstem response testing to screen for potential auditory neuropathy/auditory dyssynchrony. Universal newborn screening for critical congenital heart disease is now recommended for infants before discharge from the hospital.

#### Discharge of the Late Preterm Infant

Documentation is vital for communication among caregivers and good outcomes.

Strategies to consider for safe discharge include the following:

- Document mode of feeding.
- If breastfeeding, document lactation consult and observation.
- Establish 24 hours of successful feeding before discharge.
- Individual feedings should not exceed 20 minutes in length.
- Early weight loss should not exceed 10% of body weight or 7% of birth weight within the first 48 hours of life.
- Verify voiding and stooling.
- Document stable vital signs and blood sugar.
- Document maintenance of thermoregulation.
- Undertake hyperbilirubinemia assessment.
- Complete the car seat challenge test.
- Complete the hearing screen.
- Administer the HBV vaccine.
- Screen for critical congenital heart disease.
- Complete the blood spot (metabolic) screen.
- First-time mothers in particular require careful supervision and, when infants are leaving from an intensive care environment, should be offered a rooming-in experience.
- Document scheduled appointment for infant follow-up care.

Follow-up care should include a home nurse visit or an office visit with the primary care physician within 48 to 72 hours of discharge from the newborn nursery or 5 to 7 days from the NICU for infants

whose NICU or special care nursery hospitalization is longer than 5 days.

## LONG-TERM OUTCOMES FOR THE LATE PRETERM INFANT

Gestational age-specific long-term outcome data about LPT and heavier low-birth-weight (LBW; 1,500 to 2,499 g) infants are limited. Health outcomes for LPT infants are poorer than for full-term infants. LPT infants have higher rates of emergency department visits and rehospitalization with associated higher health care costs over the first 5 years of life. Rehospitalization for treatment of hyperbilirubinemia and for infection within the first 30 days of life is significantly greater among infants born LPT. Respiratory and gastrointestinal disorders account for over 50% of hospital admissions for this group of children. Persistent feeding difficulties following nursery discharge are also common. LPT infants who are breastfeeding require close follow-up and enhanced lactation support, including evidence-based lactation technologies and lactation strategies to promote effective feeding and growth.

Among infants with birth weights between 1,500 and 2,000 g (3.3–4.4 lb), there is reported to be an increased risk for both behavioral and psychiatric problems. Population-based studies have revealed that the risk for developmental delay or disability is 40% higher for infants weighing between 1,500 and 2,499 g at birth as compared to NBW babies. Infants born LPT and early term have higher prevalence of educational intervention program services enrollment than infants born at term, and may benefit from more frequent monitoring for developmental delays or disabilities. Educational outcomes for children born between 32 and 35 weeks' gestation are similarly affected. Although the greatest effect is among the most immature infants weighing less than 1,000 g at birth, heavier LBW children experience increased adverse educational outcomes such as academic problems, learning disabilities, physical and sensory impairments, and mental handicaps.

School performance has been studied in children born after 32 weeks' gestation. Reading and spelling difficulties are more common among children born at 33 to 36 weeks' gestation than among NBW infants. Huddy et al reported on school performance at age 7 years for a population-based cohort of children born between 32 and 35 weeks' gestation. Up to one-third of these children exhibited school difficulties; nearly 25% required additional school resources. Areas of poor performance included writing and fine-motor skills, reading, mathematics, and physical education. Rates of attention-deficit/hyperactivity disorder are nearly 2.5-fold greater than for NBW children. Behavioral difficulties are twice as common in LBW children and have been related to maternal psychological distress at 40 weeks postmenstrual age and a history of tobacco smoke exposure. Whether the effects of smoking are primary or a proxy for other environmental factors or stressors that influence the parents' well-being and ability to support their child's maturation is unclear. Among preterm children born SGA, adolescents who were under the 3% at birth were more likely than NBW term children to experience

learning and attention difficulties. SGA children between the 3% and 10% for gestational age did not experience similar difficulties. Symmetry or proportionality of growth was not related to these differences.

## Chapter 91

# HOSPITAL DISCHARGE OF THE HEALTHY TERM AND LATE PRETERM INFANT

Christina Kan Sullivan, MD; Sonia Dela Cruz-Rivera, MD

### NEWBORN DISCHARGE

The optimal timing of hospital discharge of the newborn and mother has been a subject of debate in recent years. In the United States, newborn length of stay (LOS) has varied considerably in the last 50 years because of changing perinatal hospitalization practices. Before 1920, hospital births were uncommon. By 1945, 80% of births occurred in the hospital, with an average LOS after vaginal delivery ranging from 3 to 5 days. The trend toward shorter LOS was first driven by a consumer-initiated movement between the 1960s and 1980s as an alternative to home delivery. By the 1990s, financial constraints imposed by third-party payers led to even shorter stays because insurers would not pay for hospitalizations extending beyond 24 hours for an uncomplicated vaginal delivery. The average LOS in 1992 was 2.1 days. Nearly 2 decades

later, the mean and median lengths of hospital stay for healthy newborn infants remained 2.1 and 2.0 days, respectively.

The pressure to discharge infants early based on arbitrary financial considerations has been a source of frustration for physicians and families. In addition, many medical issues related to the transition from an intrauterine to an extrauterine environment require a longer period of observation. Serum bilirubin concentration peaks at 3 to 5 days, and lactation is rarely established in fewer than 3 days. In a 1996 survey of pediatricians, 43% of respondents indicated that they had experienced adverse outcomes related to the shortened LOS. The passage of the Newborns' and Mothers' Health Protection Act of 1996 prohibited payers from restricting benefits for hospital stays to less than 48 hours after birth for vaginal deliveries and less than 96 hours for cesarean deliveries.

The American Academy of Pediatrics (AAP) first addressed the management of newborns in the hospital when the Committee on Fetus and Newborn published the first edition of *Standards and Recommendations for Hospital Care of Newborn Infants* in 1948. In 1977, the Committee recommended a 72- to 96-hour hospital LOS. The 1995 AAP policy statement detailing the minimum discharge criteria for healthy, term newborns was issued in response to the shortened hospital stay (<48 hours) with revised policy statements in 2004 and 2010 further emphasizing the concept that the length of stay of a healthy term newborn should be based on the unique characteristics of each mother-infant dyad, including the health of the mother, the health and stability of the infant, the ability and confidence of the mother to care for her infant, the adequacy of support systems at home, and access to appropriate follow-up care.

The timing of the newborn's discharge is best determined by the physician in consultation with the infant's family, and with input from the obstetrician and other care providers including nursing and lactation staff and social workers. (For further details on this subject, see Timing section.) A healthy term newborn may be ready for nursery discharge once the infant exhibits stable vital signs for at least 12 hours, has a physical examination with no abnormalities that require continued hospital care, voids, passes stool, demonstrates appropriate feeding skills, has been assessed for early-onset jaundice, completes all screening tests, and has appropriate follow-up care in place. Despite adherence to these discharge criteria for term infants, detection of significant jaundice, ductal-dependent cardiac lesions, and other problems may require longer periods of observation. Parents should be counseled about signs of illness that warrant immediate medical attention and the importance of routine follow-up care within the first week of life. Infants discharged from the hospital or birthing center within 24 hours of birth should be re-examined by a pediatric professional within 24 to 48 hours (2–3 days of age) and have a repeat newborn blood spot test performed.

### Assessing Readiness

Whether the newborn is the first or fifth child born, all new parents experience some combination of excitement coupled with exhaustion. Lack of experience, limited support systems, competing family needs, and medical complications impose additional stress on the family. Health professionals must be adept at identifying and addressing these issues so that, on hospital discharge, parents feel confident, knowledgeable, and well prepared to care for their newborn.

By the time of discharge, a physician has likely examined the newborn 2 or more times. The recommended number of assessments before newborn nursery discharge is based more on accepted clinical practice rather than on data from randomized clinical trials. From an evidence-based perspective, no well-designed randomized trials have been conducted to evaluate the efficacy of 1 versus 2 routine neonatal examinations. However, serial physical exams of the infant allow for earlier detection of anomalies and problems and give the physician the opportunity for direct communication with the family to provide information, counseling, and reassurance.

### Medical Factors

In addition to reviewing and verifying the maternal, family, and obstetric histories; documenting gestational age, anthropomorphic data, and the appropriateness of growth for the infant's gestational age; and monitoring vital signs and daily weights, the following systems particularly should be noted on physical examination:

- Head shape and signs of trauma (caput, cephalohematoma; facial bruising; asymmetric cry suggestive of nerve palsy)
- Dysmorphic features
- Eyes (red reflex, size)
- Ears (pits, tags, position, shape)
- Palate and alveolar ridge morphology, presence of natal teeth, and shortened frenulum
- Clavicles (crepitus suggestive of fracture)
- Cardiac system (location of apical pulse and murmurs)
- Femoral pulses
- Abdominal area (masses, distension; umbilicus)
- Hip (signs of dislocation or dislocatability)
- Spine (deformities)
- Foot deformities (metatarsus adductus, clubfoot)
- Genitalia and rectum
- Skin (jaundice, rash, mottling, cyanosis, birthmarks)
- General posture and muscle tone; symmetrical reflexes; irritability/consolability; limb posture and position suggestive of brachial plexus dysfunction
- Well-coordinated suck and swallow reflexes
- Ability to fix gaze and follow a human face

Newborn screening is an integral component of a neonate's initial care typically completed before the infant's nursery discharge, although infants born at home or in a birthing center will require these tests to be performed in the days after birth. The newborn blood spot screening test is performed in all hospitals in North America, although the specific conditions

screened for vary by state. Baby's First Test provides a current list of conditions included in newborn screening in each state ([www.babysfirsttest.org/newborn-screening/states](http://www.babysfirsttest.org/newborn-screening/states)). Infants whose newborn screening is performed before 24 hours of age will require an additional newborn blood spot screening test at 3 to 5 days of age. Some states routinely require a second newborn screen at this time.

Good evidence exists to support screening examination of the skin, eyes (red reflex), ears (hearing), and hips of the newborn infant. Although early detection of critical congenital heart defects (CCHD) can improve outcomes, physical examination alone will miss many infants with CCHD. Most CCHD presents with some degree of hypoxia. In 2009, the AAP and the American Heart Association (AHA) reviewed the literature on the use of oximetry screening for the detection of CCHD and concluded that "routine pulse oximetry screening on asymptomatic newborns after 24 hours of life in hospitals that have on-site pediatric cardiovascular services incurs very low cost and risk of harm." In 2011, the US Department of Health and Human Services (HHS) recommended that screening for CCHD by pulse oximetry be added to the recommended uniform screening panel (RUSP), which includes newborn metabolic screening and universal newborn hearing screening. Currently, each state is in the process of implementing this new recommendation.

All newborns should receive a hepatitis B vaccine (and hepatitis B immune globulin within 12 hours of birth if the mother is positive for hepatitis B surface antigen) and have newborn metabolic and hearing screenings as per hospital protocol and state regulations before discharge. There is evidence to support the observation that universal newborn hearing screening using physiological measures (otoacoustic emission or auditory brainstem response testing) leads to earlier identification and treatment of infants with permanent hearing loss. The AAP recommended newborn hearing screening in 1999. The Joint Committee on Infant Hearing endorsed universal screening in 2000, and by 2005 approximately 95% of newborn infants in the United States were screened before discharge. In 2008, the US Preventive Services Task Force reviewed the evidence on benefits and harms of universal screening and recommended continued screening for hearing loss in all newborns.

Maternal screening for the presence of group B streptococcus (GBS) colonization of the vagina and rectum of pregnant women at 35 to 37 weeks of gestation is pivotal to preventing newborn early-onset GBS disease (see Chapter 102, The Newborn at Risk for Infection). The second cornerstone in the prevention of early-onset GBS disease in the neonate is intrapartum antibiotic prophylaxis during labor for women who test GBS positive.

In 2010, the Centers for Disease Control and Prevention (CDC) issued revised guidelines for the neonatal management of GBS-exposed neonates. It provided management recommendations that depend on clinical appearance of the neonate and other risk factors such as maternal chorioamnionitis, adequacy

of intrapartum antibiotic prophylaxis (IAP) if indicated for the mother, gestational age, and duration of membrane rupture (see Table 91-1). Changes were made to the algorithm to reduce unnecessary evaluations in well-appearing newborns at relatively low risk for early-onset GBS disease. Intrapartum prophylaxis is considered optimal if administered at least 4 hours before delivery (Figure 91-1).

Assessment of feeding adequacy whether the infant is breastfeeding or formula feeding is an important determinant of the newborn's readiness for discharge. Coordination of the suck and swallow reflex and the frequency and duration of feeding episodes are influenced by the infant's gestation, postnatal age and physiological transition after birth, neurobehavioral state, and level of alertness. Adequacy of feeding also influences the infant's hydration status and degree of weight loss, important contributors to early or excessive hyperbilirubinemia.

Before discharge, the clinical risk of developing hyperbilirubinemia is assessed in accordance with established guidelines. Parents should be educated about neonatal jaundice—what it is, how to assess its presence, and how to contact their physician if it is noted at home. Discharge counseling gives the physician the opportunity to reinforce the importance of the follow-up visit. This visit ensures a safe transition for the newborn by identifying feeding problems, excessive weight loss, and jaundice, and reevaluating unusual or atypical findings. All abnormalities requiring further testing should be discussed in detail with the family, and appropriate follow-up arranged. Examining the newborn at least once in the parents' presence allows the health professional to point out

significant physical findings and comment on normal variations, and gives parents the chance to have their questions answered. This practice also gives the physician the opportunity to observe parent-infant and parent-parent interactions.

### Family and Environmental Factors

Observing parents' responsiveness to their new infant and their interactions with each other can provide powerful indicators of the family's comfort level with caring for their new infant. Anticipating concerns and providing thoughtful, clear answers will reassure parents and decrease any anxiety they may feel about taking their infant home.

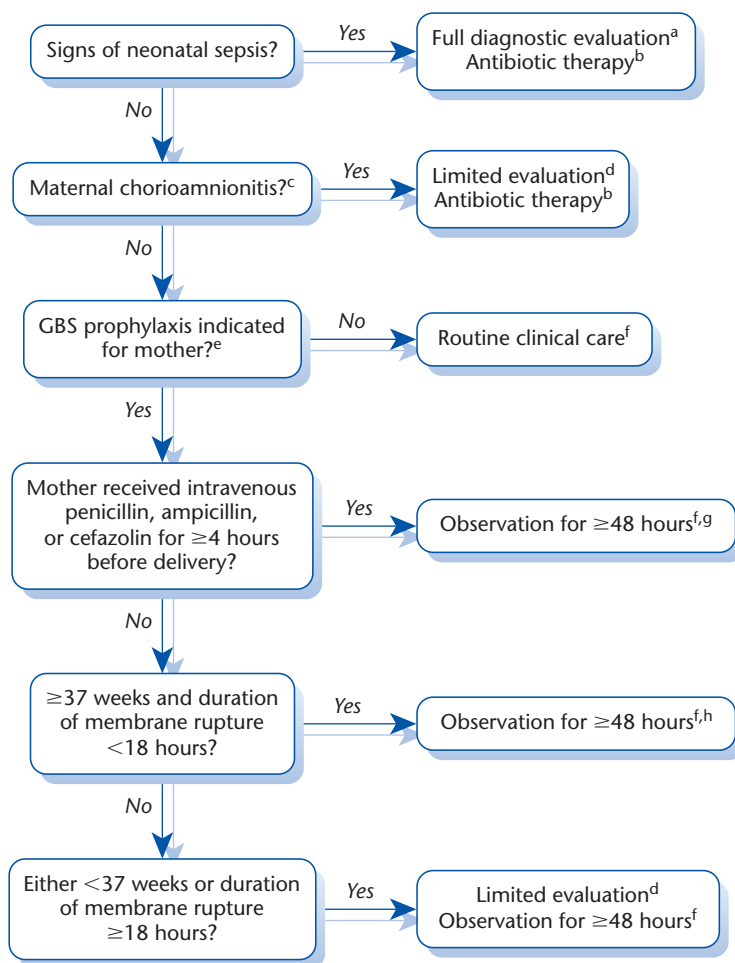

Careful attention to maternal and environmental risk factors should further influence the physician's decision about discharge readiness and may include but is not limited to inadequate social support, especially for first-time, single mothers; lack of knowledge about routine infant care and breastfeeding; adolescent parent; and presence of substance abuse or domestic violence. In addition, assessment of risk factors for postpartum depression in accordance with Bright Futures guidelines and the AAP Committee on Psychosocial Aspects of Child and Family Health must be incorporated into discharge planning. Although most physicians consider these factors, women pediatricians are 2 to 3 times more likely than men to rate these maternal and peripartum factors as highly important determinants of discharge readiness. Significant findings in these domains may not necessarily delay hospital discharge, but visiting nurse services, home visits, or earlier follow-up plans should be instituted as appropriate.

**Table 91-1**

### Strategies in the Assessment and Management of Well-Appearing Infants Born to GBS-Colonized Mothers

ADEQUACY OF INTRAPARTUM PROPHYLAXIS	REQUIRED INFANT EVALUATION	IMPLICATIONS FOR DISCHARGE PLANNING
Infants of any gestational age whose mother received <b>adequate</b> intrapartum prophylaxis (>4 hours of penicillin, ampicillin, or cefazolin).	Should be observed for >48 hours. No routine diagnostic testing is required. Well-appearing infants with a GA 35–36 weeks do not routinely require diagnostic evaluation.	Infants can be discharged home as early as 24 hours after birth, assuming that all other criteria have been met, ready access to medical care exists, and the infant's caregiver is able to comply with home observation instructions.
Mother with <b>no or inadequate</b> intrapartum prophylaxis, infant is >37 weeks' gestation, and rupture of membranes is <18 hours.	Observation for 48 hours. No routine diagnostic testing is recommended.	Infants can be discharged home as early as 24 hours after birth, assuming that all other criteria have been met, ready access to medical care exists, and the infant's caregiver is able to comply with home observation instructions.
Mother with <b>no or inadequate</b> intrapartum prophylaxis and infant is <37 weeks gestation <b>or</b> rupture of membranes is >18 hours.	Limited evaluation (blood culture, CBC with differential) and observation for >48 hours.	Infants can be discharged home after at least 48 hours of observation, assuming that all other criteria have been met, ready access to medical care exists, and the infant's caregiver is able to comply with home observation instructions.

From Verani JR, McGee L, Schrag SJ. Prevention of perinatal group B streptococcal disease—revised guidelines from CDC, 2010. *MMWR Recomm Rep*. 2010;59:1–32.

**Figure 91-1** Algorithm for secondary prevention of early-onset group B streptococcal (GBS) disease among newborns.

<sup>a</sup> Full diagnostic evaluation includes a blood culture, a complete blood count (CBC) including white blood cell differential and platelet counts, chest radiograph (if respiratory abnormalities are present), and lumbar puncture (if patient is stable enough to tolerate procedure and sepsis is suspected).

<sup>b</sup> Antibiotic therapy should be directed toward the most common causes of neonatal sepsis, including intravenous ampicillin for GBS and coverage for other organisms (including *Escherichia coli* and other gram-negative pathogens) and should take into account local antibiotic resistance patterns.

<sup>c</sup> Consultation with obstetric providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are nonspecific.

<sup>d</sup> Limited evaluation includes blood culture (at birth) and CBC with differential and platelets (at birth and/or at 6–12 hours of life).

<sup>e</sup> See Table 91-1 for indications for intrapartum GBS prophylaxis.

<sup>f</sup> If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated.

<sup>g</sup> If ≥37 weeks' gestation, observation may occur at home after 24 hours if other discharge criteria have been met, access to medical care is readily available, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until discharge criteria are achieved.

<sup>h</sup> Some experts recommend a CBC with differential and platelets at age 6–12 hours.

## COUNSELING THE FAMILY

Part of the newborn discharge process is counseling parents about how to care for their newborn infant and providing anticipatory guidance. Counseling should be tailored to the personality and practice patterns of the physician and the personality of the parents. Style notwithstanding, certain issues (summarized in Box 91-1) need to be kept in mind.

## Feeding

Physicians have the responsibility to encourage breastfeeding and should always reinforce the importance of making the decision to breastfeed.

Human milk is the best nutritional choice, and it is both economical and convenient. The most important advantage is its immunologic benefits. In addition, there is evidence that in infants at high risk for developing

**BOX 91-1 Suggested Topics for Discussion: Newborn Discharge Counseling****Feeding**

- Breastfeeding
- Bottle feeding

**Elimination**

  - Tobacco smoke
  - Lead
  - Carbon monoxide
  - Mold
  - Pesticides

**Signs of illness****Psychosocial issues**

allergies, exclusive breastfeeding for at least 4 months prevents or delays the occurrence of atopic dermatitis, cow's-milk protein allergy, and wheezing in early childhood. Breastfeeding also protects against obesity. Each month an infant is breastfed decreases the risk of childhood overweight. However, supporting the mother in whatever decision she makes with regard to feeding method is also the responsibility of physicians. (See Chapter 88, Breastfeeding the Newborn.)

**Breastfeeding**

Physicians should work with the nursing and lactation support staff to provide information to mothers to ensure successful breastfeeding. Information should include:

- Proper positioning and latch
- What the let-down reflex is
- What colostrum is, its adequacy for the early feedings, the normal feeding volume during the first days of life, and the newborn infant's stomach capacity
- The process and timing of the transition from colostrum to mature milk
- Ways to explore any culturally based misconceptions about giving the newborn colostrum, especially if the mother is hesitant to give the newborn

colostrum (common among women from Southeast Asia, parts of Africa, and South America)

- Strategies to promote successful initiation of breastfeeding when the mother plans to breast- and formula-feed
- How nursing frequency affects milk supply
- How to tell if the infant is nursing properly
- How to break suction and the meaning of nipple pain or discomfort
- Basic nipple care
- How to manage engorgement
- How to express milk manually or using a breast pump
- How to store expressed milk
- Vitamin D supplementation for the infant
- Signs and symptoms of mastitis
- Breastfeeding support groups (La Leche League, lactation consultants, Special Supplemental Nutrition Program for Women, Infants, and Children)

**Formula Feeding**

Commonly used infant formulas generally fall into 3 main categories: cow's-milk based, soy based, and hydrolyzed. Formulas are readily available in powder, concentrate, and ready-to-feed preparations, and no known advantage exists of one brand or form over another. If the parents are planning to feed their infant formula, then it is important to determine if the parents have particular concerns about one category of formula or another. Vegan parents will refuse cow milk-based formulas, whereas a family with a previous child who exhibited intolerance to a particular type of formula may request another specific formula. This preference is particularly important among immigrant families who may have used animal milk (eg, goat's milk) or formulas not typical for North America. There is modest evidence that using hydrolyzed formulas may delay the onset of atopic dermatitis in infants at high risk for atopy who are not exclusively breastfed for 4 to 6 months. Physicians should emphasize the importance of using iron-fortified infant formulas and the proper dilution of the powder or concentrate preparations (see Box 91-2). Fluoride supplementation should be given only to infants aged 6 months or older who live in communities where the fluoride concentration in the water is <0.3 ppm. Parents need to be informed that sterilizing water, bottles, and artificial nipples is not necessary if the water supply is safe and refrigeration is available. Infant formula need not be warmer than room temperature. The use of the microwave oven to warm the formula should be discouraged because it causes uneven heating. The physician should caution parents against bottle propping so as to prevent choking and aspiration.

**Elimination**

Parents should know what normal urination and bowel elimination patterns are for newborns. Parents need to be informed that after the first 2 to 3 days of life, infants should have at least 4 to 5 wet diapers per day. Stool elimination patterns are variable during this period and will depend on the type of feeding. Breastfed infants tend to have more frequent bowel movements than formula-fed infants. They can initially have as

### BOX 91-2 Preparation Checklist for Iron-Fortified Infant Formula

Please note that this information serves as a guide, but it is important to follow the manufacturer's recommendation for storage and instructions for formula mixing.

1. Wash your hands with soap and water, rinse well, and clean your work space.
2. Wash bottles, nipples, caps, rings, and preparation utensils in hot soapy water. Rinse thoroughly.
3. Place bottles, nipples, caps, and rings in a pot and cover with water, bring to a boil, and boil for 5 minutes. Remove with sanitized tongs. Allow the items to cool and air dry.
4. For READY TO FEED (RTF) formula: After washing and cleaning the top of the can, shake well and then open the can with a clean can opener. Pour the amount of RTF formula for 1 feeding into a clean bottle. Do not add water or any other liquid.
5. For LIQUID CONCENTRATED formula: After washing and cleaning the top of the can, shake well and then open the can with a clean can opener. Pour needed amount of formula into a clean bottle using ounce markings to measure formula and add an equal amount of cooled boiled water. This preparation will yield an infant formula that is approximately 20 calories/oz.
6. For POWDERED formula: Remove plastic lid, wash and clean the top of the can. Using the provided scoop, measure a level scoop of powdered formula. For each 2 oz of cooled boiled water in a clean bottle, add 1 level scoop of powdered formula. This preparation will yield an infant formula that is approximately 20 calories/oz.
7. After mixing the infant formula, attach nipple and ring to the bottle and shake well. Feed prepared formula immediately.
8. If several bottles are prepared, put a clean nipple right side up on each bottle and cover with a nipple cap. Label with date and time of preparation.
9. Refrigerate until feeding time. Follow the manufacturer's storage instructions. To warm the bottle, hold it under running warm water. Do not microwave the bottle. Use within 24 hours.
10. Throw out unused formula leftover after feeding or which has been unrefrigerated for 1 hour or more.

Adapted from *Infant Nutrition and Feeding: A Guide for Use in the WIC and CSF Programs*. Washington, DC: US Department of Agriculture; 2009.

many as 1 stool after every feeding because breast milk is more easily digested than formula. Formula-fed infants may have as few as 1 to 2 bowel movements per day. Stool frequency can change over the first few weeks and, by 1 month of age, can range from over 10 times per day to once every 4 to 7 days. Stool appearance also can change over time. It can transition from normal meconium stools to having a seedy yellow appearance over several days (Table 91-2).

**Table 91-2 Newborn Stool Patterns**

TYPE	CHARACTERISTICS	TIME FRAME
Meconium	Thick and tarry Dark green	Birth–2 days
Normal	Loose Green-brown to yellow-brown Seedy	2–5 days
Breastfed	Mushy and golden Often after each feeding Odor similar to sour milk	After 5 days

Constipation is a major concern for most parents, and the physician should discuss with families what constitutes true constipation. Parents should be reassured that straining is normal and represents the effort needed to pass stools while lying down. The infant is considered constipated if the stools are becoming hard. Regardless of the amount of straining or the interval between bowel movements, as long as the stools are soft, the infant is not constipated. Parents should be encouraged to discuss their infant's elimination patterns and stool characteristics during the follow-up visit if they continue to have concerns. Infants should be carefully examined since anterior anal displacement may be a cause for apparent constipation in infants.

Laxatives are not recommended. The physician should emphasize that honey should not be given to infants younger than 1 year because of the risk of developing botulism.

### Sleep

Newborns vary in their pattern of sleep and wakefulness. Newborns generally need 16 to 20 hours of sleep in a 24-hour period and can sleep for 2 to 4 hours at a time. During the first few weeks of life, having day-night reversal with longer periods of wakefulness during the night is common. Not until approximately 3 to 4 months of age do most infants begin to sleep through the night.

Safe sleep strategies should be emphasized to reduce the risk of sudden unexpected infant death (SUID), including sudden infant death syndrome (SIDS), which describes any sudden and unexpected death of a child under 1 year of age, whether explained or unexplained. Many of the sleep environment risk factors for SIDS, such as bed sharing and soft bedding materials, have accounted for accidental suffocation in many cases of SUID. In 2011, the AAP issued a policy statement regarding the expansion of recommendations for a safe sleep environment to reduce the risk of all sleep-related infant deaths including SIDS, suffocation from soft bedding materials, and entrapment from inappropriate sleep situations, such as becoming lodged between a mattress and headboard. Providing a safe sleep environment has the potential to reduce SIDS risk as well as

**BOX 91-3 AAP Recommendations for a Safe Sleep Environment**

1. Infants should be placed in a supine sleep position for every sleep period.
2. Use a firm sleep surface such as a firm crib mattress with a fitted sheet. Sitting devices such as car seats, strollers, and swings are not recommended for routine sleep.
3. The sleeping room may be shared with parents without bed sharing.
4. Soft objects and loose bedding should be kept out of the crib. This includes pillows, blankets, and bumper pads.
5. Pregnant women should receive regular prenatal care.
6. Avoid prenatal and postnatal tobacco smoke exposure.
7. Avoid prenatal and postnatal alcohol and illicit drug use.
8. Breastfeeding is recommended, preferably exclusive breastfeeding.
9. Consider offering a pacifier at nap time and bedtime. However, introduction of pacifier should be delayed in breastfed infants until breastfeeding has been well established.
10. Avoid overheating by ensuring that infants are dressed appropriately for the environment and avoiding overbundling and covering the face and head.
11. Infants should receive all recommended immunizations.
12. Avoid commercial devices such as wedges and positioners that can increase the risk of suffocation.
13. Do not use cardiorespiratory home monitors.
14. Supervised awake “tummy time” is recommended to allow upper body muscular development and reduce the risk of positional plagiocephaly.

reduce the risk for SUID. The HHS and the US Consumer Product Safety Commission (CSPC) have endorsed the AAP recommendations, summarized in Box 91-3.

Despite these recommendations, parents and caregivers have been resistant to implementation of supine sleep position. Common reasons include fear of choking or aspiration and perception that the infant is uncomfortable and does not sleep well in the supine position. Pediatricians should reassure parents and caregivers that coughing or gagging is a normal protective reflex to prevent choking and aspiration and that sleep arousal is an important protective response to sleep stressors.

The issue of co-sleeping remains controversial. Forms of co-sleeping vary and include bed sharing. The sleep surface can range from sharing a mat, a futon, or the floor to sleeping on a soft mattress, quilt, waterbed, sofa, or couch. These varying surfaces may not pose an equal risk to the infant. Bed sharing is increasing in frequency throughout the United States. Studies have reported that over one-third of new mothers bed-shared frequently,

with another 40% bed-sharing with their infant sometimes. Bed sharing was equally as common among mothers who smoke as those who do not in this study. Another case-controlled study found an association between bed sharing and SIDS when the infant was sleeping between 2 parents. This association was highest for infants younger than 11 weeks. This study has been criticized for having assessed bed sharing alone as a risk factor (rather than the environment within which the bed sharing occurred) and not assessing the presence of parental alcohol use at the time of bed sharing and breastfeeding in the analysis.

Sensitivity to cultural differences is necessary when obtaining sleep histories. Additionally, the assumption should not be made that families are practicing only 1 sleep arrangement over the course of the day and night. Health care professionals should consider this factor when obtaining a history on infant sleep practices and encourage parents to express their views about infant sleep and recommended sleep practices.

An alternative to sharing an adult bed or sharing a mattress is using an infant bed that attaches to the side of the adult bed and provides proximity and access to the infant but has a separate sleep surface. No current, peer-reviewed studies of such devices have been conducted, and the CSPC has not yet established safety standards for these attachable co-sleepers.

**Body Care****Umbilical Cord Care**

Evidence-based care of the umbilical cord in the postnatal period includes effective hand hygiene and keeping the cord dry and exposed to air or loosely covered with clean clothes, with the diaper folded below the umbilicus. If the umbilical cord stump becomes soiled with urine or feces, then cleansing the area with water is adequate. Studies conducted in developed countries have shown that topical antiseptics of the cord stump reduces cord colonization. However, a systematic review of randomized trials that assessed the efficacy of applying topical antimicrobial agents in the prevention of infection has not shown this practice to be superior to simply keeping the cord clean. Chlorhexidine (Hibiclens) or hexachlorophene (pHisoHex), tincture of iodine or povidone-iodine (Betadine), silver sulfadiazine, and triple dye have the most efficacy in reducing umbilical cord colonization. If topical antimicrobial agents are used, then care must be exercised because toxicity has been reported with excess or inappropriate use.

Although some hospitals and physicians continue to recommend application of alcohol to the umbilical cord, alcohol use has been shown to delay umbilical cord drying, is less effective in reducing bacterial colonization, and delays cord separation. Therefore, alcohol application is not recommended for routine umbilical cord care.

The umbilical cord stump usually separates between 8 and 15 days of age (up to 3 weeks may be normal). Minimal discharge is to be expected

thereafter. However, if significant amounts of discharge persist, it should be brought to the physician's attention. Until the cord falls off, the area should be kept dry as much as is possible to promote separation and healing. For this reason, giving infants only sponge baths is best until the cord is well healed.

### **Skin Care**

Skin lubrication is usually not necessary; however, if it is needed, then it should be limited to the use of hypoallergenic lotions. Oil-based preparations, such as petroleum-based lubricants or barriers containing zinc oxide, are more effective than water-based preparations. Talcum powder should not be used because of the danger of aspiration. The diaper area is best cleansed with warm water with each diaper change, although the use of commercially available infant wipes offers many conveniences. Although these wipes may contain chemicals, alcohol, and fragrances that can cause skin irritation, most of these products, particularly those designated as *hypoallergenic* or *sensitive*, are found to be as mild as using a wet washcloth and may be used even in the newborn period. Wipes free of fragrance, alcohol, and other chemicals, except for lotion, have been shown to be gentler than water alone. Most diaper rashes will improve with applications of zinc oxide or an antifungal preparation if the rash is not improving and has the appearance of a candidal infection. Parents should be encouraged to notify their child's health professional for a persistent diaper rash. Evidence-based clinical practice guidelines on the care of neonatal skin have been published by the Association of Women's Health, Obstetric, and Neonatal Nurses.

### **Bathing**

The purpose of bathing during the neonatal period is to remove debris. Daily bathing with soap is not recommended during this time because it may contribute to excessive drying of the skin and can exacerbate skin conditions such as atopic dermatitis. Young infants can be washed with plain water 2 to 3 times per week during the first year. However, if use of a cleanser or soap is preferred, then it should be mild with a neutral pH. Hair can be shampooed a few times weekly using a mild shampoo or body wash.

### **Nail Care**

Scissors should not be used. Nails should be filed using an emery board.

### **Dressing**

Healthy, full-term infants do not need to be dressed more warmly than an older child or adult. Parents can use themselves as a guide to determine the amount of clothing to put on the infant. A good rule of thumb is to dress the infant in 1 more layer of clothing than an adult would be wearing in the same environment. Specific guidance will need to incorporate the ambient temperature of the home where the child resides, as well as reflect the regional environmental temperatures. Questions often arise as to how warmly to dress the late preterm (34 $\frac{0}{7}$  to 36 $\frac{6}{7}$  weeks' gestation) infant. In general, the same principles apply in deciding how much clothing to use. The need

for extra clothing or use of double blankets for these infants will primarily depend on the infant's ability to maintain temperature in the ambient environment. The infant's temperature regulation will be determined, in part, by adiposity, degree of physiologic maturity, and ongoing metabolic demands. Because of high heat losses through the scalp, parents should be encouraged to cover the infant's head when going outside. Care must be exercised when swaddling a young infant. Although this method is effective for soothing a fussy infant and maintaining body temperature, an overbundled infant is at risk for hyperthermia and potentially at increased risk for SIDS if overheated during sleep.

### **Taking the Newborn Outdoors**

As soon after discharge as the mother is ready to go outside, the newborn can go out as well. Many parents are hesitant to take their newborn outside because of fear of exposure to airborne and other communicable illnesses. A common belief among many families is that an infant cannot go outside the home until the first or second set of immunizations has been received. Cultural prohibitions against outings before a certain age may also exist. Korean parents typically keep an infant indoors until the 100th day, the time when the infant's survival is thought to be more assured. Time spent in close contact with crowds should be limited and sick contacts should be avoided. Appropriate protection against excess sun exposure should also be discussed.

### **Genitalia Care—Boys**

The uncircumcised penis should be cleansed simply with water with or without a mild soap or with a diaper wipe. Retracting the penile foreskin is unnecessary because adhesions will spontaneously lyse over the first several years of life. The newly circumcised penis can also be cleansed with warm water and gentle soap with every diaper change. An antibacterial ointment or other lubricant such as vitamin A and D ointment can be applied to the area to prevent the skin from sticking to the diaper as it heals, and can reduce the small chance of infection.

### **Genitalia Care—Girls**

Recommendations suggest washing the area between the labia gently with warm water only. Diaper wipes may be used if they do not cause skin irritation, and parents should be instructed to always wipe girls from the vagina toward the anus (front to back). Parents should be informed that a white caseous discharge or even a bloody discharge from the vagina might occur in the first few days. This discharge is the result of maternal hormones that are absorbed by the fetus before delivery.

### **Safety Issues and Injury Prevention**

#### **Safe Infant Handling**

Infants are at risk for abusive head trauma (also known as shaken baby syndrome). Shaking can cause intracranial bleeding and death. Parents should be counseled to avoid handling an infant when they are overwhelmed, angry, or frustrated.

### Vehicle Safety

Vehicle seat safety should begin with the first ride home from the hospital. The physician should emphasize to parents that a car safety seat must be used at all times. The AAP Committee on Injury and Poison Prevention recommends that all infants and toddlers should ride in a rear-facing car safety seat until they are 2 years of age or until they reach the highest weight or height allowed by the manufacturer of their car safety seat. A seat with a 5-point harness provides the best fit and protection to a newborn; parents may choose an infant-only seat or a convertible car seat that accommodates the child rear facing to a higher weight and height. For AAP patient education resources on car safety seats and transportation safety, see Tools for Practice.

### Environmental Toxins

Several hazards exist in the home environment. Newborns have a unique vulnerability to certain environmental toxins, and their rapidly developing organ systems are particularly susceptible to the harmful effects of toxins. Toxic exposures of newborns differ from other age groups because of their own unique physical environment, food and water consumption pattern, and behavioral developmental stage. Parents should be informed about common environmental toxins that can significantly affect the health of their infant.

**TOBACCO SMOKE.** Tobacco smoke is a common toxic substance that is harmful to everyone, including young infants. Parents should be educated about the harmful effects of inhaled secondhand smoke, which include increased incidence of lower respiratory infections, otitis media, cough, asthma, and SIDS. The physician should stress that smoking not be allowed in the immediate environment of the infant, such as in the house or vehicle.

**CARBON MONOXIDE AND OTHER SOURCES OF INDOOR AIR POLLUTION.** Infants can be vulnerable to the effects of inhaled carbon monoxide. Intoxication from inhaled carbon monoxide can cause tissue hypoxia, which can affect multiple organ systems, with the central nervous and cardiovascular systems being the prime targets. Installing smoke and carbon monoxide detectors in the home can prevent unintentional carbon monoxide inhalation (Box 91-4). The increased popularity of scented candles and incense poses another potential hazard to young children. Burning candles with lead-core wicks have been associated with lead levels above established Environmental Protection Agency standards. Even candles with nonlead wicks pose a hazard because they often release potentially harmful organic chemicals, such as formaldehyde, acetaldehyde, and acrolein. Soot from scented candles and particulate emissions from burning incense have been linked to respiratory symptoms and irritant dermatitis in vulnerable individuals.

**LEAD.** Risk factors for lead exposure in pregnant women differ from those described for young children. The most common route and source of fetal and neonatal lead exposure is pregnancy and breastfeeding. Maternal pica during pregnancy, although rare, is an

### BOX 91-4 Sources of Carbon Monoxide Exposure

- Motor vehicle exhaust
- Unvented kerosene and propane gas space heaters
- Leaking chimneys and furnaces
- Back draft from furnaces
- Woodstoves and fireplaces
- Charcoal grills
- Gas appliances: stoves, dryers, water heaters
- Gasoline-powered generators
- Gasoline-powered equipment: lawn mowers, leaf blowers, floor polishers, snow blowers, pressure washers
- Tobacco smoke

Adapted from American Academy of Pediatrics Committee on Environmental Health. Carbon monoxide. In: Etzel RA, ed. *Pediatric Environmental Health*. 2nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2003.

identified cause of fetal lead intoxication. Although the CDC does not recommend routine blood lead testing of all pregnant women in the United States, it does encourage state or local public health departments to identify populations at increased risk for lead exposure and encourages physicians to use community-specific risk factors as a guide in determining the need for population-based blood lead testing. Routine blood lead testing of pregnant women is recommended in clinical settings that serve populations with specific risk factors for lead exposure. Common risk factors for pregnant women include recent immigration status, practicing pica, occupational exposure, use of alternative remedies or cosmetics, use of traditional lead glazed pottery, and nutritional status. Risk assessment of lead exposure should take place at the earliest contact with pregnant or lactating women. If this has not occurred during the prenatal period, then the pediatric provider should ask the mother about potential risks for lead exposure. The pediatric provider should discuss with the maternity care provider any risk factors elicited from the mother and request maternal lead screening.

Newborns who are given reconstituted infant formula prepared with tap water are at potential risk for lead intoxication. Lead still can be found in some metal water taps, interior water pipes, or pipes connecting a house to the main water pipe in the street. Lead found in tap water usually comes from the corrosion of older fixtures or from the solder that connects pipes. When water sits in leaded pipes for several hours, lead can leach into the water supply. To minimize lead exposure from drinking water, recommendations suggest flushing the water faucet in the morning for 2 minutes before using it to prepare the formula and using only cold tap water for drinking and preparing milk formula. For full recommendations from the CDC, see [www.cdc.gov/nceh/lead/tips/water.htm](http://www.cdc.gov/nceh/lead/tips/water.htm).

**PESTICIDES.** More than 900 chemicals are registered in the United States as pesticides. These substances include insecticides, fungicides, rodenticides, fumigants, and insect repellents. The developing organ systems of

young infants are especially susceptible to the harmful effects of these toxic chemicals. Routes of exposure for newborns are inhalation and skin absorption by contact. Infants of parents with occupational exposures to pesticides such as those who work on farms, pesticide applicators, or landscapers are at increased risk of exposure to pesticides. Prevention includes washing work clothes separately from the infant's laundry, changing out of work clothing, and washing with soap and water before coming into close contact with infants and children (Box 91-5).

### Signs of Illness

Parents should know when and how to contact the physician or the pediatric office in case of an emergency. Parents should be advised to contact the physician for the following reasons:

- Fever (rectal temperature  $\geq 100.4^{\circ}\text{F}$  [ $\geq 38^{\circ}\text{C}$ ])
- Persistent coughing or breathing difficulty
- Cyanosis (Few parents understand what the terms *cyanosis*, *blue*, or *dusky* skin color actually mean. Explanations should also include the differences between peripheral [acrocyanosis], circumoral, and central [body core] cyanosis. The physician should therefore explain these potential concerns and assess the parents' understanding.)
- Sudden change in level of alertness, activity such as persistent irritability, or lethargy
- Feeding difficulties
- Persistent or projectile vomiting
- Diarrhea
- Jaundice
- Seizures
- Decreased urine output
- Umbilical cord problems
- Unusual skin rash or skin mottling

### Psychosocial Issues

The first few weeks at home with a newborn can be stressful to all family members but particularly new

parents. The need for an adequate support system at home cannot be overemphasized. Sources of extra help might be family members, close relatives and friends, or hired help. Close support persons can assist with infant care and household chores. For families who do not have the advantage of having an adequate support system, community agencies are often available to assist them. Information on public and private groups that can provide services to these families is usually available through the social service department. It is reported that 11% to 18% of women experience postpartum depressive symptoms. It is therefore important that the pediatrician assess the mother for depressive symptoms.

Devoting a large amount of time to discharge counseling is often difficult because of time constraints and shorter hospital stays. However, allowing sufficient time for parents to ask questions and for these questions to be addressed is important. Whether it is the initial or a subsequent meeting between the physician and the parents, the physician must be able to ascertain the kind of professional relationship the family desires, as well as anticipate needs relative to care of their newborn and integration as a family unit.

Of paramount importance is the personal interaction between the physician and the parents before the discharge of the infant from the hospital. Providing reading materials to parents is relatively easy, but handouts can never replace personal interaction, which can lay the groundwork for a lasting professional relationship between the physician and the parents.

## FOLLOW-UP NEWBORN CARE

### Timing

Follow-up of newborns within the first week of life—typically within 48 to 72 hours of nursery discharge (by 3–5 days of age) for newborns going home from the hospital within 48 hours of birth, newborns who are breastfeeding, or newborns with health concerns that place them at risk for early medical problems (such as the late preterm infant)—is crucial to assessing the adequacy of hydration and feeding patterns and to assessing bilirubin levels and degree of weight loss. Studies have shown that newborns who receive early follow-up visits were less likely to be rehospitalized within the first 10 days of life for jaundice or dehydration. The AAP recommends that all healthy, full-term (37–41 weeks), singleton newborns whose birth weight is appropriate for gestational age and who are discharged in fewer than 48 hours should have a follow-up appointment preferably within 48 hours, and no later than 72 hours of discharge. For late preterm infants (34–36 weeks), the recommendation for the follow-up visit is within 24 to 48 hours of hospital discharge because they are at greater risk of neonatal morbidity and mortality than term infants. For infants who are discharged more than 48 hours after childbirth, the first office visit may occur within 2 to 4 days of discharge. In some communities, hospitals routinely offer families the option of bringing the infant back to the hospital for a postdischarge visit. These guidelines apply equally to formula-fed and breastfed infants. The AAP Section on Breastfeeding

### BOX 91-5 Safe Pesticide Practices

- Wash work clothes separately from other laundry.
- Wash work clothes with detergent and hot water before wearing them again.
- Wash hands and arms after putting clothing into washing machine.
- Change clothing and wash with soap and water before picking up or playing with your children.
- Store pesticides in an area safe from children.
- Cover children's skin if they are with you at work.
- Keep the children and their toys and playthings indoors when there is nearby aerial spraying or spraying that may drift near the house.
- Children and teenagers should avoid work that involves mixing or spraying pesticides.

Adapted from American Academy of Pediatrics Committee on Environmental Health. Pesticides. In: Etzel RA, Balk SJ, eds. *Pediatric Environmental Health*. 3rd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2012:515–548.

states: “All breastfeeding newborn infants should be seen by a pediatrician or other knowledgeable and experienced health care professionals at 3 to 5 days of age . . . and again at 2 to 3 weeks of age.”

### Purpose

Although the main purpose of the visit is to detect problems such as jaundice, feeding difficulties, and excessive weight loss or poor weight gain, this visit also provides another opportunity for parents to have their infant examined, to be reassured about minor physical variations, and to have their questions answered, and for the physician to assess parent-infant interaction and the adaptation of the parents to their new role.

The 2010 policy statement from the AAP states that the purpose of the follow-up visit is to:

- Weigh the infant; assess the infant’s general health, hydration, and degree of jaundice; identify any new problems; review feeding pattern and technique; and obtain historical evidence of adequate urination and defecation patterns for the infant
- Assess the quality of mother-infant attachment and details of infant behavior
- Reinforce maternal or family education in infant care, particularly regarding infant feeding and safety such as breastfeeding, back to sleep, and child safety seats
- Review the results of outstanding laboratory tests, such as newborn metabolic screens, performed before discharge
- Perform screening tests in accordance with state regulations and other tests that are clinically indicated, such as serum bilirubin measurement
- Verify the plan for health care maintenance, including a method for obtaining emergency services, preventive care and immunizations, periodic evaluations and physical examinations, and necessary screenings
- Assess for parental well-being including postpartum depression in the mother

Families need reassurance that they are responding adequately to their infant’s cues. Even a simple discussion of the normal variations in a newborn’s schedule with regard to timing of feedings, sleep, and stool consistency and frequency can alleviate concerns and empower parents to be better observers, which can ultimately decrease stress and allow greater enjoyment of parenthood.

### Barriers

On hospital discharge, physicians should ensure at a minimum that the following barriers to adequate follow-up care are identified and addressed:

- Lack of transportation to medical care services
- Lack of easy access to telephone communication
- Non-English-speaking parents

Inadequate communication from the hospital to the community-based provider about a newborn’s birth, medical history, and relevant laboratory data may be the result of a lack of a clear mechanism for communication, as well as the fact that some families have not identified a postdischarge provider at

the time of discharge. Gaps in parental knowledge have been attributable to a decreased opportunity for parental education with shorter LOS and lack of physician awareness for early follow-up.

Despite the published recommendations for follow-up of newborns, many do not have a posthospital follow-up visit within the recommended time frame and do not receive appropriate management of hyperbilirubinemia. Only approximately 50% of healthy term newborns who need phototherapy based on the AAP practice parameter actually receive it. This circumstance results, in part, from the reality that even guidelines based on an evidence-based approach do not translate readily into changes in standards of care and improved practice. The AAP recognizes that “knowledge is essential but not sufficient to produce behavior change” and has developed the *Safe & Healthy Beginnings* toolkit, which contains a discharge readiness checklist. This resource was developed to help physicians prepare a newborn for discharge and to close the gap between theory and practice in the management of issues that are critical to promoting a seamless transition from hospital discharge to home during the critical first week of life.

## Chapter 92

# FOLLOW-UP CARE OF THE HEALTHY NEWBORN

Deborah E. Campbell, MD

The timing of initial follow-up care of newborns after nursery discharge is based on several factors: the newborn's gestational age and postnatal age at hospital discharge, whether the newborn is breastfeeding or formula feeding, the quality and efficiency of the newborn's feeding abilities, and the presence of risk factors that predispose to complications or an increased risk for early hospital readmission. In a report by Jackson et al, 8% of indigent urban neonates monitored developed signs of illness in the early postnatal period. Of these, 31% developed symptoms after 24 hours of age, emphasizing the importance for early postdischarge follow-up care. Among insured newborns with access to an integrated system of health care, follow-up care within 72 hours of nursery discharge has been found to be protective against the risk for early rehospitalization. The Pregnancy Risk Assessment Monitoring System (PRAMS) collects data about newborn discharge and the timing and adequacy of postdischarge follow-up care from 27 states participating in this Centers for Disease Control and Prevention program. In 2002 the percentage of newborns discharged from the hospital within 48 hours of birth ranged from 50% to 70%. Significant geographic variation in newborn infant follow-up rates, ranging from 58% to 90%, was noted across the United States. PRAMS also found that during the period between 2000 and 2002, several states improved in the proportion of infants receiving follow-up within the first week of life. Five states (Arkansas, Florida, Illinois, North Carolina, and Utah) made significant strides in improving adherence with first-week follow-up care for newborns during this period of monitoring. Also notable is that only 2 states, New York and Rhode Island, exceeded the 90% threshold for infants having received *sufficient well-baby care* during the first 9 months of life in the time period studied. On average, newborns stay in the hospital for 3.4 days. During 2009 to 2010, 93.2% of mothers reported that their newborns had a follow-up pediatric visit within 1 week after the birth. The proportion of mothers reported pediatric visits within the first week varied by race and ethnicity; the lowest rates being reported by non-Hispanic American Indian/Native Alaska mothers. Recent investigations have focused on the group of infants identified as at greatest risk for early neonatal mortality and morbidity—the late preterm (34<sup>0</sup>/<sub>7</sub> to 36<sup>6</sup>/<sub>7</sub> weeks' gestation) and early term (37<sup>0</sup>/<sub>7</sub> to 38<sup>6</sup>/<sub>7</sub> weeks', gestation) infants. Among late preterm infants there was no change in the rate of early discharge between the years 2000 (40%) and 2005 (39%). Variation in individual state practices regarding the timing of newborn discharge persisted as did variation in discharge timing related to insurance coverage

and hospital type. Nonteaching hospitals were more likely to discharge infants early if they were uninsured or insured through a health maintenance organization. Among infants insured through state Medicaid programs there was a similar, though not statistically significant trend toward earlier discharge. Delayed pediatric follow-up care remains a common problem in both urban and suburban settings. Despite policy guidelines and efforts to increase awareness of the importance of appropriate discharge planning and early postnursery follow-up care for late preterm and term infants discharged home within 48 hours of their birth, delays in the necessary postnatal follow-up continue.

Early follow-up is important in terms of reassessing the newborn for signs of illness related to congenital malformations that are not evident at birth or during the immediate newborn period. New mothers report they experience new physical and emotional problems following technology-intensive births with high rates of cesarean deliveries and other interventions, get limited support from husbands/partners and others, must return to employment within a short period of time, and are often unable to start or continue breastfeeding as they want. Parental adaptation to their new role and an assessment of the mother's and the newborn's readiness to leave the hospital are additional aspects to consider in determining how soon follow-up should occur. Maternal depression and the potential for peripartum abuse of the mother are additional potential risk factors that support the need for early follow-up. Infant care practices of concern, such as co-sleeping, are being reported with increasing prevalence. Research regarding perceptions about mother and baby readiness for discharge from the hospital emphasizes the importance of mutual decision making about the optimal time for discharge and follow-up care. Recommendations concerning the optimal timing for the initial postdischarge pediatric visit are consensus based, formulated from reported cohort and population study outcomes for newborns who have been discharged within 48 hours of birth.

The initial follow-up visit may be provided in the newborn's home, a hospital-affiliated newborn follow-up clinic, or in the pediatrician's office. The guiding principle for this phase of care is that it should be a physician-directed source of continuing medical care for the mother and baby. An important factor in the decision about where and how the initial care should occur is identification of barriers to the parents' ability to comply with early postnatal follow-up. Issues of access to care remain significant despite the 1996 Newborns' and Mothers' Health Protection Act and the Health Insurance Portability and Accountability Act of 1996, which stipulate that access by the mother and her newborn to appropriate follow-up health care must be ensured, and that insurers cannot deny newborns coverage to avoid complying with these federal mandates. Numerous studies document the effect of federal regulations and the newborn's insurance status on health care utilization and the timeliness of postdischarge newborn follow-up. Common factors identified across studies are the level of maternal education, families living in poverty or residing in poor communities with limited

access to care, other children at home, and immigrant or non-English-speaking status.

Barriers to timely follow-up of newborns during the first week of life have been explored through focus groups with families and physicians. Physicians and parents identify issues of communication and information, processes of care, and parent knowledge and education as critical factors. Parents value and can assimilate information about early warning signs in regard to their newborn. Pediatricians play an important role in setting office practices regarding the timing of newborn follow-up care. Despite a long-established recommendation regarding the need for early follow-up after a short newborn nursery hospitalization, many physicians still counsel parents that follow-up within 1 to 2 weeks after nursery discharge is acceptable. Other barriers are limited office hours or inadequate hospital and community resources to provide timely home health or public health nursing visits, particularly on weekends and holidays. This barrier can prevent a family's adherence with a recommended 24- to 48-hour (3–5 days of age) follow-up visit or home visit. Assistance with scheduling the initial follow-up appointment, particularly among Medicaid recipients, has been shown to be an effective strategy to parental adherence with infant follow-up.

Goals of 48- to 72-hour follow-up care appointment include the following:

- Assess the newborn's general health, hydration, and degree of jaundice, and identify any new problems.
- Review the newborn's feeding pattern and feeding skills, including observation of a breastfeeding episode for appropriate positioning, latch-on, coordinated sucking and swallowing, and any maternal concerns regarding clinical problems that can disrupt effective breastfeeding (newborn state regulation; cracked or sore nipples; mastitis; engorgement, flat, or inverted nipples, prior breast surgery).
- Review the pregnancy and family (including genetic) history, pertinent prenatal diagnostic test results, and the newborn's nursery course to ensure identification of risk factors requiring further assessment and follow-up care. (This review is particularly important if the infant is new to the practice.)
- Assess the infant's voiding and stooling patterns.
- Assess maternal/caregiver–infant interaction and details of newborn behavior (state regulation and adaptation), maternal and family adaptation to the infant, family functioning, and signs of maternal/caregiver depression or family distress.
- Reinforce education about newborn care, exclusive breastfeeding, appropriate newborn feeding practices, and safety, including safe sleep practices.
- Combination breastfeeding and formula feeding shortens the duration of breastfeeding.
- New mothers experience a variety of perceived barriers and challenges that contribute to early breastfeeding cessation.
- Review which newborn screening tests were performed during the infant's newborn hospitalization. Infants discharged home before 24 hours of milk feedings require a repeat blood spot test by

3 to 5 days of age. Some states routinely require a second blood spot test be obtained when the infant is 3 to 5 days of age.

- The optimal time for screening for congenital hypothyroidism is between 48 and 96 hours of life. Specimens collected in the first 24 to 48 hours of life may lead to false-positive thyroid-stimulating hormone elevations when using screening test methods.
- If the infant referred on initial newborn hearing screening or if screening was not performed during the birth hospitalization, ensure that the family has an outpatient appointment for a hearing screening.
- Review or, if not done during the newborn hospitalization, complete the risk assessment for severe

hyperbilirubinemia. The determination of risk factors for hyperbilirubinemia in conjunction with physical examination and transcutaneous or total serum bilirubin level are effective in reducing the risk for acute bilirubin encephalopathy (Figure 92-1).

- In 2011, the US Department of Health and Human Services issued recommendations that screening for critical congenital heart disease (CCHD) should be added to the panel of conditions for which all newborn infants are screened. Many states have passed legislation requiring universal screening for CCHD before newborn nursery discharge. Physicians should be aware of the regulations in their state and affiliated delivery hospital practices, and perform a careful physical examination on all newborn infants, since

## Is the Baby at Risk for Severe Hyperbilirubinemia?

## Does This Baby Need Phototherapy?

Source: Maisels MJ, McDonagh AF. Phototherapy for neonatal jaundice. *N Engl J Med*. 2008;358:920–928

- These guidelines are based on limited evidence.
- Guidelines refer to use of *intensive* phototherapy, which is the use of high levels of irradiance in the 430- to 490-nm band (usually  $30 \mu\text{W}/\text{cm}^2$  per nm or higher) delivered to as much of the newborn's surface area as possible.
- *Use total bilirubin.* Do not subtract direct reacting or conjugated bilirubin.
- ***Risk factors referred to in the graph key indicate specific risk factors that increase the likelihood of brain damage at different bilirubin levels.*** These risk factors include isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase deficiency, asphyxia, respiratory distress, significant lethargy, temperature instability, sepsis, acidosis, or albumin less than 3.0 g/dL (if measured).
- For well babies born between 35 and 36 6/7 weeks, you can adjust total serum bilirubin (TSB) levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for newborns closer to 35 weeks and at higher TSB levels for those closer to 37 6/7 weeks.
- It is an option to provide phototherapy in the hospital or at home at TSB levels 2 to 3 mg/dL below those shown, but *home phototherapy should not be used in any newborn with risk factors listed herein.*

**Figure 92-1, cont'd**

neither prenatal nor postnatal screening will detect all congenital cardiac disease.

- Review with the mother or caregiver the baby's ongoing preventive health care needs, including immunizations and scheduling of other evaluations as needed, based on prenatal testing or postnatal assessment.
- Review the importance of parental, sibling, and other caregiver vaccinations against influenza, pertussis, and other communicable diseases in providing additional protections for the young infant. Late preterm infants born between 34 and 35 weeks' gestation may also be eligible for prophylaxis against RSV infection if they have siblings under age 5 or will be in day care during the height of RSV season (November through March) and are less than 90 days of age.
- Review with the mother/caregiver how to access care in an emergency and for routine or nonurgent issues.
- Review with the mother/caregiver the adequacy of family resources, including the newborn's health care coverage. Solicit and discuss any parent-identified concerns or issues related to the newborn or family.

Neonatal weight loss is often an issue of concern for families and physicians, particularly because dehydration and failure to thrive are significant risks for the newborn who is experiencing feeding difficulties or whose mother has lactation failure. Controversy exists about routine monitoring of a newborn's weight because some physicians express concern about unnecessary interventions, interruption of exclusive breastfeeding, and parental anxiety in response to early weight loss. McKie et al noted that implementation of regular neonatal weight monitoring among a cohort of infants in Scotland did not reduce breastfed among the cohort of women and infants studied. Another recent cohort observational study of 961 term newborns born in Scotland found that, by 5 days of age, 34% had regained their birth weight; 17% were more than 5% below birth weight, with 3% of these infants more than 10% below birth weight. The mean weight loss for this group of babies was 50 g (1.67 oz). At 12 days of age, more than 80% had regained birth weight, with most gaining an average of nearly 200 g.

The degree of weight loss was correlated with newborn birth weight; term neonates with lower weights exhibited minimal weight loss. Comparison of early neonatal weight-loss patterns between breastfeeding and formula-feeding term newborns demonstrated a median weight loss of 6.6% among those breastfed versus 3.5% for those formula-fed. Typically, breastfed babies lose more weight and take longer to regain their birth weight compared with formula-fed babies; upper limits of weight loss were 12% of birth weight for breastfed babies versus 8% for formula-fed babies. The median time of maximal weight loss and time to regain birth weight were also longer for the breastfed infant. Flaherman et al determined that

breastfed infants who lose 4.5% or more of their body weight during the first 24 hours of life are 3.6 times more likely to exhibit weight loss in excess of 10% of their birth weight during the newborn nursery hospitalization. In general, weight loss of more than 3% in the first 24 hours of life or greater than 7% at 48 hours of age warrants careful assessment.

A complete physical examination should be performed. Key aspects of the examination include the following:

- Eyes for opacities including cataracts (red reflex)
- Heart and lungs for congenital heart disease (cyanosis, murmur, tachypnea, femoral pulses, tachycardia)
- Hips for dysplasia (Barlow and Ortolani tests)
- Skin for evidence of jaundice, drying of the umbilical cord, lesions suggestive of infection, and pallor
- Nervous and musculoskeletal systems for state regulation, activity and response to stimulation, tone and reflexes, asymmetry limb posture, position, and movement
- Assessment of the newborn's hydration status, particularly for newborns at risk for feeding difficulties (prematurity, poor feeding or poor cuing in regard to hunger, signs of illness or anomalies not previously identified)

Subsequent follow-up primary care appointments are typically based on specific newborn and parent needs. Routine follow-up after the first week postdischarge newborn visit for the healthy term newborn without health issues is scheduled for 6 to 8 weeks of age. Components of the assessment at that health visit include a thorough physical examination, with special attention focused on evaluation of the eyes for opacities including cataracts (red reflex), heart for congenital heart disease (cyanosis, murmur, tachypnea, femoral pulses), neurodevelopmental screening, and hips for dysplasia (Barlow and Ortolani tests). Results of the newborn screening test and any other interim screening or diagnostic studies performed should be reviewed to ensure that further evaluation or treatment is not required.

## SECTION TWO

# Assessment and Physical Examination of the Newborn

### Chapter 93 MATERNAL MEDICAL HISTORY

*Harpreet Kaur, MD; Deborah E. Campbell, MD*

Familiarity with the maternal history is crucial to identifying risk factors that can contribute to illness in, or later health risk for, the infant. The health of the mother directly affects the well-being of the fetus and newborn. The physician should learn about the family constellation and the mother's physical and mental health, life stressors, support systems, and developmental adaptation to the prospect of becoming a parent. The physician should also inquire about the family's preparations for the infant, including infant safety, and identify resource needs and the availability of family and community support. Anticipatory guidance will encompass care of the infant in the hospital after delivery (including any specialized testing), infant feeding choice, early infant state regulation and temperament, newborn screening routines, and the timing of postdischarge follow-up care for the infant.

### PRECONCEPTION AND ANTENATAL HISTORY

Comprehensive care for a newborn requires a thorough review of the maternal history in preparation for examination of the newborn. Unfavorable maternal social history, poverty and limited education, lack of adequate prenatal care, poor nutrition, and inadequate pregnancy weight gain, as well as exposure to nicotine, alcohol, prescription medications and illicit substances, domestic violence, and other environmental or occupational exposures, contribute to adverse pregnancy outcomes. Evidence of the harmful effects of maternal exposure to environmental toxins on fetal well-being is increasing. Infant mortality and other adverse birth outcomes (congenital defects, premature birth, and low birth weight) have been linked to various environmental toxins (pharmaceuticals, alcohol, nicotine, mercury, lead, nitrates, manganese, polychlorinated biphenyls, and other pollutants). Maternal race, ethnicity, and history of recent immigration are additional factors that influence pregnancy risks and outcomes. Acculturation over time moderates the benefits seen among recent immigrant women who benefit from close community support during pregnancy. The literature that documents the adverse health effects of chronic stress and its effect on minority, particularly black, women is also increasing. Fetal growth

is affected by generational influences with regard to both low birth weight and cardiovascular risk.

### Alcohol Use and Binge Drinking

The physician examining the newborn may suspect maternal drug abuse when treating an infant exhibiting irritability, poor feeding, vomiting, high-pitched crying, or tremors. Fetal alcohol spectrum disorders remain the largest cause of nongenetic disability worldwide and are 100% preventable. Among developed countries, the rate of fetal alcohol syndrome (FAS) is reported as 1 in 1,000 live births. In the United Kingdom, where two-thirds of pregnant women admit to alcohol consumption during pregnancy, 1 in 100 infants born is diagnosed with fetal alcohol syndrome. Studies conducted by the Centers for Disease Control and Prevention (CDC) have shown that 0.2 to 1.5 cases of FAS occur for every 1,000 live births in certain areas of the United States. The CDC 2010 Behavioral Risk Factor Surveillance System survey found that 7.6% of pregnant women (1 in 13) and 51.5% of nonpregnant women reported drinking alcohol in the past 30 days; 1.4% of pregnant women report binge drinking (4 or more drinks on an occasion at least 1 time in the past 30 days). Among women of childbearing age who are not practicing birth control, more than 50% report using alcohol, and 12.4% report binge drinking. (See Chapter 104, Prenatal Drug Use: Neonatal Effects and the Drug Withdrawal Syndrome.)

### Assisted Reproduction

The mode of conception is an additional aspect of the pregnancy history that provides the physician with valuable information. Assisted reproductive technology (ART) has become a routine aspect of fertility care for families worldwide. Based on data from the National Survey of Family Growth (NSFG), the percentage of women aged 15 to 44 who had ever used infertility services increased from 9% in 1982 to 15% in 1995, then declined to 12% in 2002, and remained at that level in 2006 to 2010. Estimates suggest that between 1% and 5% of all neonates born are conceived through ART. Outcomes for these pregnancies vary with assistive reproductive technique, the underlying cause for the female or male infertility, and the need to use donor eggs. This information is important in determining the infant's future care and may influence the parents' adaptation to parenthood and necessitate extra care on the part of the pediatrician should the parents choose to keep this information confidential from other family members. Singleton infants born from ART pregnancies are more likely to be preterm or low birth weight and experience

similar complications related to these conditions. ART pregnancies that result in multiple births are also at risk for prematurity, low birth weight, and increased perinatal mortality and morbidity and have higher rates of congenital malformations and epigenetic alterations (imprinting defects). (See Chapter 81, Assisted Reproductive Technologies, Multiple Births, and Pregnancy Outcomes.)

### Pre-existing Health Conditions

A maternal history of chronic medical conditions such as diabetes, hypertension, severe anemia, and thyroid disease can have perinatal effects on the fetus and can influence the postnatal course for the newborn. Box 93-1 provides an outline of maternal and family factors that can affect pregnancy and infant health. A woman with poorly controlled diabetes is at risk for pregnancy complications that can affect the neonate in several ways, causing fetal macrosomia that places the infant at risk for dystocia at delivery, metabolic derangements after birth, respiratory distress, hyperbilirubinemia, and, if the mother has pre-existing diabetes, a variety of birth defects. Obesity, recognized as an important health concern, disproportionately affects blacks, Hispanics, poor people, and those with a low level of education. In addition to the well-established health risks, obesity in pregnancy confers additional risks to the mother, fetus, and newborn that continue into childhood as well as adult life. Obesity has been shown to be an independent risk factor for a multitude of adverse outcomes, including maternal, fetal, and neonatal death.

Chronic hypertension and hypertensive disorders of pregnancy increase the risk for preterm delivery and fetal growth restriction. Abruptio placenta can cause neonatal anemia, perinatal distress, and permanent neurologic injury. Maternal asthma increases the risk for fetal death and spontaneous abortion. Infants born to women with Graves disease may develop neonatal thyrotoxicosis as a result of transplacental passage of maternal antibodies. Similarly, infants born to women with autoimmune thrombocytopenia are at risk for intraventricular hemorrhage. An infant diagnosed with congenital heart block may be the first indication that the mother has an underlying autoimmune disorder.

The maternal medical history can also influence the counseling provided to the mother and family. A woman with a history of epilepsy, particularly if she continues to experience seizures, requires specific guidance on how to care for her infant safely, especially if she is alone with the infant. The paternal history also influences considerations regarding risks to the infant's health and need for follow-up evaluations. A paternal history of a genetic disorder or carrier status may necessitate specific infant screening. Paternal age (young or advanced) has been associated with the risk for infant low birth weight in addition to de novo or abnormal methylation of paternally imprinted genes. Environmental exposures may affect both parents, with exposure to organic solvents, pesticides, and radiation causing the greatest concerns for fetal development.

Infants born to women on medications may experience complications from drugs that cross the placenta and accumulate in fetal tissues. A baby born to a woman with hypothyroidism who is taking propylthiouracil may exhibit transient neonatal hypothyroidism. Maternal

medication use can further affect the clinical care of an infant and can assist in the diagnosis of an infant born with specific signs or stigmata. A history of antiepileptogenic medication use with carbamazepine, valproic acid, or phenytoin is associated with risk for embryopathy. Maternal depression has the potential to affect the fetus and newborn, as does the treatment of this condition in the pregnant woman. The increasing use of antidepressant therapy during pregnancy, particularly selective serotonin reuptake inhibitors, for treatment of depression has not been associated with an increased risk for major congenital malformations but is linked to an increased incidence of neonatal abstinence syndrome and poor neonatal adaptation.

### PRENATAL TESTING AND DIAGNOSIS

Approximately 10% of all infants born will be found to have a birth defect. Maternal prenatal screening can therefore provide valuable information that can identify potential risk factors for the infant, as well as detect conditions that are treatable during pregnancy, with the opportunity to improve the perinatal outcome. For a variety of reasons, many pregnant women undergo sonography during their pregnancy. The information gathered from 1 or more sonographic studies may identify a fetal abnormality or aberrant fetal growth. In some instances, further evaluations and a diagnosis will have been known before the infant's birth. In other cases, a suspected abnormality will require evaluation after the infant's birth to confirm its presence, to identify other abnormalities, and to determine a course of care. Advances in prenatal sonography, magnetic resonance imaging, and prenatal genetic diagnosis have contributed to the identification of suspected or confirmed anomalies in many more infants at the time of their birth. Depending on the suspected anomaly or problem, the infant may be cared for in the newborn nursery and undergo evaluation there rather than be separated from the mother in a neonatal unit.

For some infants, prenatal diagnosis may provide an opportunity for fetal therapy to correct an abnormality, with the goal of improving the chance for fetal survival or improving the long-term outcome for the infant after birth by preventing or reversing a process that can affect organ function. Monochorionic twins are at risk for twin-to-twin transfusion syndrome because of vascular interconnections. Fetal therapy involving laser ablation of these vessels can improve the chance for survival of the donor twin. A variety of fetal interventions for potentially life-threatening fetal malformations offers promise in improving survival rates and functional outcomes. Maternal testing may also provide valuable information. Discordancy in a twin gestation or abnormal umbilical vessel Doppler studies should alert the physician to potential postnatal problems. A report of polyhydramnios or oligohydramnios should raise specific differential diagnoses for consideration.

### FAMILY HISTORY

The family medical history provides the physician with valuable information. Numerous hereditary conditions can affect the newborn. The physician should obtain a detailed history regarding illnesses or conditions that are present in family members. Congenital heart disease, pyloric stenosis, or Hirschsprung disease in a

    - Tay-Sachs disease, Canavan disease
  - Renal disease
- Conditions linked to ethnic background or consanguinity

previous child increases the risk for these conditions in subsequent pregnancies. Diseases such as hemophilia, sickle cell disease, Tay-Sachs disease, and cystic fibrosis are inherited. Parents should be asked if they are related because consanguinity increases the risk for autosomal recessive disorders. The increased availability of genetic counseling and testing affords families the opportunity for a more comprehensive evaluation when a history of multiple pregnancy losses exists. As a result, genetic information is available for many more infants who have chromosome-related syndromes and balanced translocations at the time of their birth. Routine pregnancy testing includes a quad screen (see Chapter 80, Perinatal Preventive Care: Fetal Assessment) and may entail serial sonography for fetal growth, as well as a fetal evaluation for the presence of anomalies.

Review of the pregnancy history should also include the results of maternal screening during pregnancy, including maternal syphilis serology, group B *Streptococcus* colonization, and hepatitis B status, as well as possibly HIV and tuberculosis status (depending on specific state public health law requirements and maternal risk factors), blood type, and Rh and antibody (Coombs) tests. Additional test results to consider are the maternal complete blood count, blood chemistries, studies performed in the evaluation of the mother with hypertensive disease in pregnancy, diabetes-screening studies (glucose challenge and glucose tolerance tests), and a test for thyroid disease. The physician should inquire about a maternal history of herpes infection, treatments received, and any episodes during the current pregnancy (Table 93-1). Perinatal HIV prevention is a critical component of prenatal care required for all women, given that women are the fastest growing group of individuals with HIV diagnoses in the United States and in many countries worldwide. It is estimated that the percentage of pregnant women tested over a 12-month period ranged from 51.2% to 60.7% in 3 recent surveys.

Estimates indicate that 6,000 to 7,000 HIV-positive women give birth annually in the United States. Of particular importance is the fact that 40% of infected infants are born to women whose HIV status was not known during the pregnancy. Knowledge about the

woman's HIV status is also important because this status will guide breastfeeding counseling and identify infants who are in need of perinatal treatment with zidovudine to reduce the rate of HIV transmission to the infant, as well as postnatal testing to determine whether HIV infection of the infant has occurred. Specific state public health policies augment the CDC and Institute of Medicine recommendations regarding requirements for maternal counseling and testing during pregnancy and labor and requirements for postnatal evaluation and treatment of at-risk infants.

Congenital syphilis, a serious, preventable disease, continues to be an important public health and clinical care challenge. Up to 40% of pregnancies in women with untreated syphilis result in fetal or perinatal death. Despite the continued increase in rates of primary and secondary syphilis among both men and women, intensive state public health surveillance programs for pregnant women have reduced the number of congenital syphilis cases. The CDC recommends screening women at high risk for syphilis during the first and third trimesters of pregnancy. Screening for syphilis at delivery primarily ensures that infants born to women in whom syphilis previously was either unidentified or untreated are identified and treated. Follow-up evaluation of an at-risk infant born to a woman with positive serologic testing is necessary to ensure appropriate management.

Maternal immunization history should be reviewed. Vaccination of pregnant women is permissible with inactivated virus or bacterial vaccines or toxoids. Live-virus vaccines are generally contraindicated during pregnancy because of the theoretical risk for virus transmission to the fetus. Inactivated influenza vaccination is recommended during the winter season. Routine administration of a dose of Tdap during each pregnancy irrespective of the patient's prior history of receiving Tdap is now recommended. To maximize the maternal antibody response and passive antibody transfer to the infant, the optimal timing for Tdap administration is between 27 and 36 weeks of gestation although Tdap may be given at any time during pregnancy. For women not previously vaccinated with Tdap, if Tdap is not administered during pregnancy, Tdap should be administered

**Table 93-1** Effect of Maternal Infections on the Newborn

INFECTION	EFFECT
Rubella	IUGR, microcephaly, rash, congenital heart disease
Tuberculin test	Asymptomatic mothers with positive purified protein derivative require a chest radiograph to rule out active tuberculosis (TB). Active TB is a contraindication to breastfeeding.
Hepatitis B surface antigen	Babies born to mothers with infection need hepatitis B vaccine immediately after birth and hepatitis B immune globulin within 7 days. These infants require hepatitis B surface antigen (HBsAg) and anti-HBsAg at 9–18 months to check for infection.
Serologic test for syphilis	Increased risk for stillbirth, IUGR, hydrops, and premature labor. Treatment with penicillin if (a) physical laboratory or radiographic evidence of active disease, (b) positive testing on direct fluorescent antibody staining on cord blood, (c) cerebral spinal fluid–VDRL is positive, or (d) serum nontreponemal titer is at least 4-fold higher than that of the mother.
HIV	Treatment during pregnancy and delivery decreases the incidence. Newborns are screened at birth and started on prophylactic therapy.
Group B <i>Streptococcus</i>	Greatest risk for sepsis
Gonorrhea, chlamydia	Conjunctivitis

IUGR, intrauterine growth restriction; VDRL, Venereal Disease Research Laboratory.

immediately postpartum. Breastfeeding mothers may receive Tdap; there is no risk to the infant. Specific guidance regarding current CDC Advisory Council on Immunization Practices recommendations is available at [www.cdc.gov/vaccines/pubs/preg-guide.htm](http://www.cdc.gov/vaccines/pubs/preg-guide.htm).

## INTRAPARTUM COURSE

The intrapartum course can also influence the infant's care and anticipated postnatal course. A maternal history of prolonged rupture of the membranes or meconium-stained amniotic fluid provides important details that guide the newborn's initial management and alert the physician to the level and scope of observation or assessment required. A meconium-stained neonate who exhibits intrapartum fetal distress is at increased risk for hypoglycemia, respiratory distress, pulmonary hypertension, and pulmonary air leak (pneumothorax, pneumomediastinum). Female infants born by cesarean delivery as a result of breech presentation require close surveillance for developmental dysplasia of hips.

## DURATION OF PREGNANCY

Gestational age is calculated in completed weeks as the time elapsed between the first day of the last menstrual period and the day of delivery. If pregnancy was achieved using ART, then gestational age is calculated by adding 2 weeks to the conceptional age. Ultrasound in the first trimester provides a reliable estimation of the gestational age. *Full term* is defined as any neonate whose birth occurs from the beginning of the first day of the 38th week (day 260) through the end of the last day of the 42nd week (day 294) after the onset of the last menstrual period. By convention this means that an infant born from 37½ to 42½ weeks' gestation is classified as *term*. Prematurity is defined as less than 37½ weeks' gestation. Postterm infants are at greater risk for perinatal morbidity and death.

## Chapter 94

# PHYSICAL EXAMINATION OF THE NEWBORN

Harpreet Kaur, MD; Deborah E. Campbell, MD

Examining the newborn in the presence of the parents provides an opportunity to demonstrate the infant's physical and developmental characteristics and to model positive infant–caregiver behaviors. This interaction with the family also affords the physician the chance to initiate a health supervision partnership with the family.

## ASSESSING THE NEWBORN IN THE DELIVERY ROOM

The first assessment of the newborn infant, including assignment of the Apgar score, is usually performed in the delivery room to identify any signs of distress or delay in the infant's initial transition and to assess for the presence of visible malformations. Inspection of the newborn for obvious malformations is important because this will further guide the immediate care needs of the newborn and determine the level of nursery care required. A newborn with a cleft palate will require admission to a special or neonatal intensive care unit for evaluation and specialized feeding management. In contrast, a baby born with an isolated

limb deformity may be admitted to a newborn nursery for care and evaluation. Healthy newborns who do not exhibit transitional difficulties are able to remain with their parents in the labor-delivery-recovery suite for an extended period before admission to the newborn nursery. This allows for early initiation of skin-to-skin care immediately after birth and supports breastfeeding within the first hour following delivery. During the first 30 to 60 minutes after birth, infants are typically quite alert and active; thus this period is an opportune time to initiate breastfeeding. Otherwise healthy infants who are at risk for early neonatal hypoglycemia, small-for-gestational-age babies, infants of diabetic mothers, and late preterm infants (34<sup>0</sup>/<sub>7</sub> to 36<sup>6</sup>/<sub>7</sub> weeks' gestation) should feed, either breastfeeding or with infant formula, within the first hour following delivery.

Most (85%–90%) newborns do not exhibit any difficulty in their postnatal physiologic transition. Among the 10% to 15% who do experience problems are infants who are preterm, those who are delivered by cesarean section or who require instrument-assisted delivery, and newborns who exhibit signs of perinatal distress or whose mothers have pregnancy complications that affect the fetal environment and placenta function. Chapter 109, Assessment and Stabilization at Delivery, provides a comprehensive discussion about resuscitation and stabilization of the newborn who is having difficulty with the initial postnatal transition.

In the delivery room, rapid assessment of the newborn's gestational age may be performed using a rapid scoring system that assesses maturity by examining the creases in the sole of the foot, size of the breast nodule, nature of scalp hair, cartilaginous development of the earlobe, labial development in female newborns, and scrotal rugae and testicular descent in male newborns (Table 94-1). In addition to inspecting the infant for malformations or signs of distress that may necessitate admission to a special or neonatal intensive care unit, the examiner should review the prenatal history for antenatal findings that warrant further evaluation.

## Assessing the Gestational Age

The Ballard score provides neuromuscular and physical maturity scores to determine gestational age (Figure 94-1). Studies have shown that the Ballard

**Figure 94-1** Maturational assessment of gestational age (new Ballard score). (From Ballard JL, Khoury JC, Wedig K, et al. New Ballard score, expanded to include extremely premature infants. *J Pediatr*. 1991; 119:417-423. Reprinted by permission of Dr Ballard and Mosby-Year Book, Inc.)

score is most consistent with the prenatal ultrasound and last menstrual period in estimating the gestational age within a 2-week range and is most accurate when performed within the first 12 hours of life. Newborn infants who experienced intrauterine stress related to a variety of maternal medical conditions (hypertension, preterm labor) or environmental exposures (nicotine, cocaine, heroin, antenatal steroids) may demonstrate accelerated neurologic maturation in comparison with the level of physical maturity.

## Approach to Physical Examination of the Newborn

### Clinical Observation

Initial observation should occur with the newborn undressed and in a quiet state. The color, spontaneous movements, cry, posture, tone, and respiratory pattern should be observed. The infant should be observed for symmetry of movements of the arms and legs. The optimal time to conduct this examination is following a feeding when the baby is in a quiet, alert state.

The examiner should observe the newborn's appearance. Does the baby seem normal and comfortable? What is the infant's color? Are any skin lesions present? What is the newborn's tone and activity level? Is the baby alert and responsive? Are any atypical or abnormal eye movements noted?

Observing the infant's transition through different states can assist in the identification of some abnormalities, such as a facial palsy. This can occur because of fetal compression against the maternal pelvis affecting a branch of the facial nerve or because of hypoplasia or agenesis of the depressor anguli oris muscle. These infants exhibit asymmetry of the mouth during crying or inability to close the eyelid on the affected side.

Engaging the parents during the assessment of the infant enhances communication and parental involvement. The room should be warm and have adequate lighting available to facilitate examination of the skin for jaundice or lesions. It is important when performing the neurologic examination to make sure the infant is alert and awake. Examining the baby at the mother's bedside also provides an opportunity to talk to the parents about the infant's immediate care needs and health concerns during the first week of life, including neonatal jaundice, early weight loss, and common skin findings such as erythema toxicum, milia, benign pustular melanosis, and various birth marks. The parents can be encouraged to ask questions they may have about their newborn's development and health. The parents can also be educated about conditions that require immediate medical care.

Allowing the newborn to grasp the parent's or examiner's finger provides an opportunity to assess the strength of the newborn's grasp and reduces the tendency for reflexive startle response to exogenous stimulation. The resting posture for the healthy full-term newborn is generally symmetrically flexed. A newborn who has sustained a clavicular fracture or brachial plexus injury may seem to have an abnormal or atypical posture or limb position. Preterm newborns, babies who are ill, or neonates with conditions affecting their neurologic function may seem hypotonic.

### Listening to the Cry

Physicians should train themselves to listen to and assess an infant's cry. A normal cry is strong. Hoarseness, weakness, or an unusual high- or low-pitched cry may indicate a laryngeal or neurologic abnormality. A repetitive, inconsolable cry is considered abnormal. A high-pitched cry is often related to a central nervous system problem, whereas a low, throaty cry suggests congenital hypothyroidism; a *catlike* cry is significant for cri du chat syndrome. A weak, poorly sustained cry may occur in an infant who is ill, neurologically impaired, or born with Down syndrome. Babies experiencing neonatal abstinence may be extremely irritable and difficult to console. Infants who remain inconsolable with comforting measures warrant assessment for an underlying cause, such as pain, sepsis, drug withdrawal or in utero substance exposure, and neurologic abnormalities.

### Body Measurements

In all newborns, weight, length, and head circumference are part of an assessment of the adequacy of fetal growth and are a baseline for evaluation of subsequent growth. Measurements should be plotted on standardized, gestational age-specific growth charts. Three major sets of growth charts have been developed that are most commonly used around the world: British/European (Tanner and Whitehouse), the 2000 Centers for Disease Control and Prevention (CDC) Sex-Specific Growth Charts in the United States, and the World Health Organization International Reference charts. Although the 2000 CDC Sex-Specific Growth Charts may be used for this initial evaluation, the physician should recognize that the data points for term gestation are a composite of data derived for infants weighing more than 1,500 g at birth and do not reflect gestation-specific data that are necessary to properly evaluate adequacy of fetal growth and to identify infants at particular risk based on inadequate or excessive fetal growth. This distinction is particularly important for the late preterm infant, 34 to 36 weeks' gestation, who is often cared for in a regular newborn nursery. No evidence has been found demonstrating large genetic differences in birth weight among various populations; thus the use of separate, race-specific reference curves, even in situations in which race is associated with other risk factors such as poor nutrition or low socioeconomic status, is not supported. A newborn whose birth weight is below the 10th percentile or more than 2 standard deviations below the mean is considered small for gestational age. Large-for-gestational-age infants have birth weights above the 90th percentile (weights more than 2 standard deviations above the mean) for their gestational age. The National Center for Health Statistics reports that the mean birth weight ( $\pm 1$  standard deviation) for singleton infants born in the United States during 2004 was 3,316 g ( $\pm 570$  g) or 7 pounds, 5 ounces. Of note, this represents a gradual reduction in the mean birth weight among healthy, term infants over time.

Racial and ethnic variations can be found in birth weight, with non-Hispanic white and Hispanic infants having higher mean birth weights than non-Hispanic black infants. Mean ( $\pm 1$  standard deviation) birth weights were reported as 3,375 g ( $\pm 554$ ), 3,316 g ( $\pm 548$ ), and 3,115 g ( $\pm 628$ ) for non-Hispanic white,

Hispanic, and non-Hispanic black infants, respectively. Of note, since 1990, the birth weight among singleton infants has declined by 1%, with the highest declines in birth weight among non-Hispanic white infants.

Length is measured by placing the baby supine on a commercially available measuring device. Care must be taken to ensure that the baby's head is touching a fixed object and the body and legs are extended. Normal measurement of length ranges between 47 and 55 cm. The midpoint of a newborn's body is typically considered to be at the level of the umbilicus, and the crown-pubis-to-pubis-heel ratio is 1.7:1. This ratio is altered in disorders such as chondrodystrophy.

Measuring the baby's head circumference requires placing a disposable measuring tape around the occipital-frontal circumference (OFC): across the forehead, just above the eyes, and over the most prominent part of the occiput. This measurement should be repeated 2 or 3 times and the results averaged to yield the OFC. A normal OFC measures 33 to 37 cm in a full-term infant. Benign familial megalencephaly, a normal variant, is the most common cause of a large head, a trait typically inherited from the father. Chest circumference, if measured, is usually 1 to 2 cm less than the head circumference.

### Skin

Newborn skin is pink and uniform. (See Chapter 95, Neonatal Skin.) Vernix is a white, cheesy material composed of cellular and other debris that is usually present at birth, although it is absent in postterm (>41 weeks' gestation) infants. Lanugo is fine body hair visible on a newborn that begins to thin after 28 weeks. Abundant earlier in gestation, lanugo diminishes with increasing gestation. Acrocyanosis is a bluish discoloration of a newborn's extremities, which is normal for a healthy newborn during the first few hours after delivery, disappearing over the course of the next 24 hours, and represents relatively sluggish circulation of blood through the peripheral structures when they are cold. Acrocyanosis is not a valid indicator of an infant's oxygen status.

Mongolian spots are bluish-green, well-demarcated areas of pigmentation visible most often on the buttocks, back, or shoulders of darker-skinned infants. The skin should be examined for evidence of jaundice, meconium staining, edema, petechiae, and hemangiomas. Skin mottling may be a sign of sepsis or shock.

Erythema toxicum is a common neonatal rash that typically appears during the first week of life and resolves without treatment by 5 to 7 days of age. It begins as an erythematous, macular rash that develops into a small papule on an erythematous base. The papule can sometimes become vesiculopustular. Transient neonatal pustular melanosis is another common skin finding, with characteristic lesions that evolve from small vesiculopustules to hyperpigmented macules, flat dark areas that resemble freckles that may be surrounded by fine desquamating skin. Some infants are born with hyperpigmented macules, whereas others develop pustules after birth that rupture during the first few days, with subsequent formation of the hyperpigmented macules. These lesions fade over the course of 3 weeks to 3 months without treatment. Milia are small white, firm papules noted on the upper cheeks, nose, and chin that are caused by blockage of the sweat ducts

in the skin. Nevus simplex is a pink discoloration of the skin, typically involving the eyelids, glabella, and nuchal areas and resulting from vascular ectasia.

### Head

The newborn's head can vary in shape and symmetry, depending on the intrauterine position, presentation at delivery, degree of molding, or need for an instrument-assisted delivery (forceps or vacuum extraction). Infants born by cesarean or breech delivery often have a symmetrical, round head, in contrast to infants born vaginally, whose head shape is often elongated in the occipital area, with overriding sutures.

### Sutures and Fontanels

Sutures are strong, flexible fibrous tissue connecting the 6 major bones of the skull. The coronal, lambdoid, sagittal, metopic (frontal), and squamosal sutures are shown in Figure 94-2. Fontanels are the points at which the suture lines intersect. The sutures and fontanels are necessary for the infant's brain growth and development. As the brain grows, it exerts pressure on the skull bones, causing new bone deposition along the suture lines. Remolding of bone along the periosteal and dural surfaces of the sutures shapes the head as it grows.

**Figure 94-2** Normal skull sutures and fontanels.

Skull growth occurs perpendicular to a suture such that growth along the coronal suture increases the skull's anterior-posterior diameter; whereas growth along the sagittal suture increases the skull's width. After brain growth is complete at approximately 2 years of age, the fibrous sutures are replaced by rigid bone.

During childbirth, the flexibility of the fibers allows the bones to overlap their edges, without compressing and damaging the infant's brain, as the head passes through the birth canal. Sutures are easily palpable at birth when the bone edges are not widely separated. Overriding sutures palpated after delivery typically resolve with time. Premature fusion of sutures may be palpable as a prominent edge.

Fontanels, the wider spaces at the intersections of the sutures, are usually felt as *soft spots* on the head and vary in size. Large fontanels may indicate hypothyroidism, hydrocephaly, in utero malnutrition, rickets, or a genetic disorder. The posterior fontanel is located at the junction of the lambdoid and sagittal sutures. It is usually triangular, less than 0.5 cm at birth, and closes shortly after birth. The diamond-shaped anterior fontanel is located at the junction of the sagittal and coronal sutures, measures approximately 4 to 6 cm at birth, and closes at about 18 months of age. A depressed anterior fontanel is a late sign of dehydration, whereas a bulging fontanel can be normal in a crying baby but may be associated with hydrocephalus, birth injury, intracranial bleeding, or infection, or it may be present as a late sign of raised intracranial pressure. A third fontanel may sometimes be present between the anterior and posterior fontanels and can be associated with congenital anomalies.

Molding is a common occurrence associated with cephalic presentation during vaginal delivery, although it may also be present in a neonate delivered by cesarean section after a prolonged labor. Molding typically resolves 2 to 3 days after birth (Figure 94-3). Birth-related deformations (deformational, positional or nonsynostotic plagiocephaly) of the skull may also be present at birth. Characterized by forehead asymmetry, this deformation is caused by compressive or restrictive forces along the coronal or lambdoid sutures in utero or during the birth, or is related to subsequent positioning. Prematurity and low birth weight, multiple fetuses, congenital muscular torticollis, a restrictive uterine environment, congenital anomalies, neurologic disorders, and medical conditions that limit fetal head movement are risk factors for deformational plagiocephaly. Infants with positional molding will have an open suture and frontal and temporal prominence on the same side as the affected suture, and frontal flattening on the opposite side. The skull has the appearance of a parallelogram.

Caput succedaneum is caused by constricting pressure on the fetal head during passage through the birth canal. It produces a diffuse subcutaneous edematous swelling of the soft tissue that may cross suture lines and usually resolves within several days. Neonatal extracranial hemorrhages occur in 2 forms: as a cephalohematoma or a subgaleal hemorrhage. A cephalohematoma is a subperiosteal hemorrhage that is a soft, fluctuant cyst-like swelling usually occurring after a difficult or instrument-assisted delivery. Cephalohematomas occur in 1% to 2% of live births and are more common in male first pregnancies (Figure 94-4). Most resolve within a period

**Figure 94-3** Molding.

**Figure 94-4** Cephalohematoma.

of 6 weeks to several months. Babies who sustain a large cephalohematoma require monitoring of hematocrit and bilirubin levels. Cephalohematomas typically calcify at the edges during resolution, giving an impression of a depression of the skull in the center, with eggshell-like bony margins on palpation. Skull films should be obtained only if fracture is suspected.

Subgaleal hematoma is a serious, but less common, complication usually associated with vacuum-assisted delivery. It is caused by rupture of the emissary veins, which are connections between the dural sinuses and the scalp veins. Blood accumulates between the epicranial aponeurosis of the scalp and the periosteum. This potential space extends forward to the orbital margins, backward to the nuchal ridge, and laterally to the temporal fascia. This potential space can easily accommodate up to one-half of the blood volume of a neonate; therefore, monitoring blood pressure, hematocrit, bilirubin, and signs for hypovolemia, bleeding, and shock is necessary. Table 94-2 provides a comparison of the characteristics that differentiate caput from extracranial hemorrhages.

Craniosynostosis is the premature fusion of 1 or more of the cranial sutures; it can occur as part of a syndrome or as an isolated defect. Typically, an infant exhibits an asymmetrical head shape and has a palpable ridge along a suture line. The premature closure or absence of 1 or more of the sutures prevents normal head growth and may constrain brain growth. Compensatory growth occurs along the open sutures, resulting in craniosynostosis and distortion of the head shape. Head growth is restricted in the plane that is perpendicular to the fused suture and enhanced in the plane parallel to the fused suture (Figure 94-5). Synostosis involving more than 1 suture is often associated with a syndrome and requires early intervention to limit the risk for increased intracranial pressure and neurologic impairment. Sagittal synostosis caused by premature closure of the metopic suture is the most frequent form of craniosynostosis,

with a male predominance (3:2 male-to-female ratio) and occurs most commonly in white infants. Numerous syndromes and chromosomal mutations are associated with craniosynostosis. Table 94-3 describes the differences between craniosynostosis and nonsynostotic plagiocephaly.

**Figure 94-5** Cranial shapes associated with premature suture closure.

**Table 94-2** Characteristics of Caput Succedaneum, Cephalohematoma, and Subgaleal Hematoma

FEATURE	CAPUT SUCCEDANEUM	CEPHALOHEMATOMA	SUBGALEAL HEMORRHAGE
Cause	Pressure of the fetal head on the cervix during labor; causes decreased blood flow to the area and results in edema	Subperiosteal hemorrhage	Suture diastasis; ruptured emissary vein caused by fragmentation of parietal bone; skull fracture
Suture line Appearance	May extend suture lines Localized soft tissue edema, with poorly defined outline; pitting edema	Does not cross suture line Soft, fluctuant, localized swelling, with well-defined outline; initially firm but more fluctuant after 48 hr	Can extend to orbits and neck Firm to fluctuant; ill-defined borders; may have crepitus or fluid waves
Timing	Usually present at birth; does not progress and resolves in 48–72 hr	Increases after birth for 24–72 hr and resolves over 2–3 wk; sometimes not evident immediately after birth	Progressive after birth and resolves over 2–3 wk
Blood loss	Minimal	Occasionally severe; coagulopathy suspected	May be massive, especially if coagulopathy is present
Complications	Rare	Intracranial bleed; jaundice	Hypovolemic shock

**Table 94-3** Features of Craniosynostosis Versus Nonsynostotic Plagiocephaly

	CRANIOSYNOSTOSIS	NONSYNOSTOTIC PLAGIOCEPHALY
Head shape	Asymmetrical head because the growth is restricted perpendicular to the fused suture	Flat spot on the back or 1 side of the head caused by remaining in a single position for too long
Cranial suture	Fusion of sutures	Normal sutures
Diagnosis	Radiographic examination or computed tomographic scan	History and physical examination
Treatment	Surgery	Positioning, helmets
Cause	Unknown	External molding caused by back sleeping, restrictive intrauterine environment, muscular torticollis, prematurity

Craniotabes is an abnormal softening or thinning primarily of the parietal bones in preterm infants that gives a sensation of a ping-pong ball on gentle pressure. It normally disappears in a few weeks. Persistence beyond a few weeks is considered pathologic and should alert the physician to suspect rickets, syphilis, osteogenesis imperfecta, marasmus, hypervitaminosis A, and hydrocephalus. A bruit on auscultation over the temporal arteries and anterior fontanel can be heard in cases of high-output cardiac failure or neuro-pathologic abnormality. Transillumination is not part of the routine examination but should be performed in a newborn with an unusually large or asymmetrical head or if a widely patent suture or fontanel is present. Diagnoses associated with craniotabes include subdural effusion, subdural hematoma, hydrocephalus, hydranencephaly, porencephaly, increased intracranial pressure, and even skull fractures and nutritional deficiencies. Imaging studies such as neurosonography, computed tomography, and magnetic resonance imaging are important tools in evaluating the newborn to identify potential intracranial disease.

### Scalp

The scalp should be inspected for abrasions or lacerations caused by internal monitor placement or birth-related injury. Aplasia cutis congenita is a skin disorder in which an infant is born with a missing patch of skin. The affected area is usually covered with a thin transparent membrane, is well defined, and is not inflamed. Although aplasia cutis congenita may occur anywhere on the body, 80% of these lesions occur on the scalp. When aplasia cutis congenita occurs on the scalp, an associated skull defect may be present underneath, which may be an isolated finding or associated with other syndromes or disorders.

The physician should examine the hair for its color, texture, distribution, and directional pattern. Reddish or blond hair in a black infant may indicate albinism. Hair color is usually uniform; random patches of white hair may be familial in origin, but a white forelock should alert the physician to consider Waardenburg syndrome (associated pigment defect, deafness, and retardation). The frontal margin of the hairline may vary. Some infants will have extensive hair distribution involving the face, arms, and torso, which typically resolves over a few months. These infants may

also have synophrys—fusion of the eyebrows in the midline—a finding that should prompt the physician to consider whether the infant has other stigmata of Cornelia de Lange syndrome. The posterior hairline has a more consistent limitation. Hair roots distributed below the neck creases, particularly at the lateral margins, can be associated with syndromes involving a short and webbed neck. Normally the direction of hair growth is consistent with a single parietal hair whorl positioned off center, 1 to 2 cm anterior to the posterior fontanel and most often to the left. If the hair whorl is in the midline, if more than 1 whorl is present, or if the whorl is located inferior to the posterior fontanel, then it may be associated with an underlying brain abnormality. Unusual or extremely wiry or unruly hair in a small-for-gestational-age infant with microcephaly and unusual facies suggests the presence of a genetic disorder.

Encephalocele is a neural tube defect characterized by saclike protrusions of the brain and the membranes that cover it through openings in the skull. These defects are caused by failure of the neural tube to close completely during fetal development. Encephaloceles cause a groove down the middle of the skull, or between the forehead and nose, or on the back side of the skull.

### Face

The face should be inspected in its entirety, and the individual facial structures should be closely examined as well. The examiner should evaluate the size, shape, and position of the eyes, ears, nose, mouth, and chin. The face can be divided into thirds, with one-third encompassing the forehead, one-third the eyes and nose, and one-third the mouth and chin. Abnormalities of individual features in isolation are generally not significant, but a combination of atypical features increases the likelihood of an associated syndrome.

### Eyes

Examination of the newborn eye can sometimes be difficult. Examining the eyes is easiest when the baby is in a quiet alert state because the eyes are often open spontaneously. The physician can also take advantage of the vestibular reflex that is elicited by holding the newborn upright, supporting the baby's head with a hand, and gently rocking the neonate back and forth.

If the baby is in a quiet state, then the eyes will open. Occasionally, a newborn will open the eyes when given a finger or pacifier on which to suck. Newborns typically exhibit a dysconjugate gaze, given that eye movements are often not coordinated until approximately 3 to 4 months of age.

The sclera is usually white, although it may appear blue in a premature newborn or yellowish in a jaundiced newborn. Neonates with osteogenesis imperfecta also have a blue sclera. Subconjunctival hemorrhages can occur normally during labor and delivery and resolve over time. These hemorrhages are the result of rupture of small blood vessels near the surface of the bulbar conjunctiva. The iris appears dark blue until 3 to 6 months of age, when eye color may change. The iris should be perfectly circular, with the pupil located centrally and visible striations radiating out from the center. The iris should be examined for evidence of a defect or coloboma. A coloboma is a hole in a structure of the eye, such as the lens, eyelid, iris, retina, choroids, or optic disc. The hole is present from birth and can be caused when a gap between 2 structures in the eye in the fetus fails to close up completely before birth. It can be an isolated abnormality or a feature of CHARGE syndrome (coloboma, heart disease, atresia choanae, retardation of growth or development, genitourinary tract anomalies, and ear anomalies) when it occurs in association with other anomalies. The presence of white spots may be abnormal and should prompt a formal ophthalmologic evaluation. Pupil response to a light stimulus occurs consistently after 32 weeks' gestation but may be present from 28 weeks' gestation. The pupillary response to light and symmetry of eye movement should be checked. The cornea and lens should be clear. Opacification can occur as a consequence of congenital glaucoma, infection, cataract, or trauma. Brushfield spots, also referred to as a *speckled iris*, are small white spots that are slightly elevated on the surface of the iris arranged in a concentric ring around the pupil. These spots occur in healthy children but are far more common among those with Down syndrome.

All infants and children should have an examination of the eye's red reflex performed by a physician or trained professional before discharge from the nursery and during subsequent routine health supervision visits. Current recommendations are that an infant's eyes should be examined for the red reflex from the newborn period through 3 months, then at 6 months, continuing on episodically through early childhood. The red reflex test uses light transmitted from an ophthalmoscope through all the transparent parts of the eye, including the tear film, cornea, aqueous and vitreous humor, and lens. An ophthalmoscope with the lens power set at zero is focused on the pupil from a distance of 18 inches. To be considered normal, the red reflex in both eyes should be symmetrical. Dark spots in the red reflex, a blunted red reflex on 1 side, lack of a red reflex, and the presence of a white reflex (retinal reflection) are all indications for immediate referral to an ophthalmologist for a dilated examination. Leukocoria, a white pupillary reflex visible on the ophthalmoscopic red reflex test, is the most common

presenting clinical sign in retinoblastoma. Newborns in high-risk groups, including those with a family history of retinoblastoma, congenital cataract or glaucoma, congenital retinal dysplasia, and genetic or familial eye disease, should have a dilated eye examination, preferably by an ophthalmologist. Newborns in whom the parent or the observer describes a history suspicious for presence of leukocoria should be referred to an ophthalmologist because a small retinoblastoma or other serious lesion may develop in a subtle fashion.

Congenital cataracts may result from intrauterine infection or can be inherited as a dominant trait from an affected parent. Gonococcal ophthalmia neonatorum tends to develop after the first few days of life but can occur later. *Chlamydia trachomatis* infection, another cause for eye drainage, occurs after the first week. Chemical conjunctivitis caused by silver-nitrate ointment instillation in the eyes is usually self-limited. Tearing is not normal until 2 months of age. Tearing or persistent crusting after the first 2 days requires evaluation for congenital glaucoma (associated photophobia and cloudy cornea), infection, corneal abrasion, and obstruction of the nasolacrimal duct (NLD). In congenital glaucoma, elevated eye pressure pushes fluid into the cornea, causing it to swell and become hazy. Parents may be the first to notice clouding or whitening of the cornea.

An epicanthal fold, a small web of tissue overlapping the nasal corner of the eye, is typical among infants of Asian descent, may be familial in 1% of the non-Asian population, and is a clinical feature in several conditions: Down syndrome, fetal alcohol syndrome, Turner syndrome, phenylketonuria, Williams syndrome, Noonan syndrome, Rubinstein Taybi syndrome, and blepharophimosis syndrome. Upward slant of the outer edge of the eye is another ocular finding associated with trisomy 21. Hypertelorism (widely separated eyes) and hypotelorism (narrowly separated eyes) are other features to be assessed.

### Ears

The normal ear location is determined by drawing an imaginary horizontal line from the inner canthi of the eyes perpendicular to the vertical axis of the head. If the helix of the ears lies below this line, then the ears are low set and can be associated with other syndromes or anomalies. Hairy ears are seen in infants of diabetic mothers. Visualizing a tympanic membrane is not an essential part of a newborn examination and is often not possible because of the presence of vernix or amniotic fluid.

Abnormalities of the external ear include malformation such as microtia, malposition, preauricular pits, tags, and sinus tracts. Malformations may be familial, an isolated finding, or part of a syndrome. The degree of development of the external ear is among the physical characteristics used in determining a neonate's maturity at birth. The physician should examine the ears' size, shape, and position and assess for the presence of abnormalities such as a preauricular skin tag or sinus (ear pit).

Preauricular tags and sinuses are reported to occur in 5 to 10 infants per 1,000 live births. An isolated

preauricular sinus is typically considered a benign malformation. Although these are considered common minor anomalies, the physician should thoroughly examine the affected newborn and review the prenatal and family history for evidence of other malformations or a history of hearing impairment. Renal ultrasonography should be performed in any newborn with an ear anomaly accompanied by other dysmorphic features, family history of deafness, maternal history of gestational diabetes, or a defined syndrome.

Although there is consensus regarding the need to evaluate the urinary tract of a newborn with a major ear malformation or a preauricular tag or sinus accompanied by other abnormalities, controversy exists regarding the need for renal sonography if the newborn's only anomaly is a preauricular tag or sinus. Two publications argue against the need for renal sonography in babies with isolated minor ear anomalies, reporting that the prevalence of renal anomalies among individuals with preauricular tags and sinuses is similar to the reported incidence of renal abnormalities in the general population. The most prudent approach in view of the current lack of a definitive conclusion is for the physician to thoroughly examine the newborn with an isolated minor ear anomaly for evidence of other malformations or dysmorphism, the presence of which should prompt evaluation with a renal ultrasound.

### Nose

Nasal flaring is a frequent finding in the neonate who is transitioning from the fetal physiologic environment to independent extrauterine cardiorespiratory function and denotes the newborn's attempt to decrease airway resistance. Because newborn infants are obligate nose breathers, nasal patency should be verified. Gently blocking each nostril while the mouth is closed and then listening for air movement through the unobstructed nare is an important part of the physical examination. Alternatively, a wisp of cotton can be placed in front of each nostril and observed for movement. If the physician is unsure from these maneuvers that the nasal passage is patent, then a soft 6-French catheter may be inserted into each nare to check for patency. Babies with bilateral choanal atresia exhibit respiratory distress and cyanosis immediately after delivery; the distress is relieved with crying or if the mouth is opened.

The nasal bridge should be inspected for flattening and the presence of any midline defects. Flattened nasal bridge can be a normal variation or associated with congenital syphilis, Down syndrome, or Williams syndrome. Congenital obstruction of the nasolacrimal drainage system is common, although symptomatic infants with signs of nasal obstruction or respiratory distress are rare. The 2 forms of lacrimal system obstruction observed are NLD obstruction and dacryocystocele. Reports suggest that up to 20% of newborns develop symptoms of obstruction of the nasolacrimal system. It is usually caused by persistent membranous obstruction near the lower end of the NDL; the most distal portion of the duct near its exit to the nose is most typically involved. The obstruction may be unilateral or bilateral. Presenting signs include

either or both eyes appearing moist, tearing, crusting on the eyelashes, and, over time, chronic or intermittent infections and periocular redness and irritation. Lacrimation increases during the first 2 to 3 weeks of life. Consequently, NLD obstructions may not become evident until the newborn is 3 weeks of age. Spontaneous resolution occurs in more than 95% of affected infants. Differential diagnosis of the newborn with persistent tearing and mucopurulent discharge includes congenital glaucoma, an eyelash or eyelid abnormality, and conjunctivitis. Congenital dacryocystocele is a less common form of NLD obstruction that is caused by distention of the nasolacrimal sac. It is characterized by a bluish-gray cystic swelling below the medial canthus of the eye and may be confused with a vascular malformation. Acute inflammation in and around the lacrimal system develops in 20% to 60% of neonates within the first days of life.

Studies have demonstrated the efficacy of medical management with warm compresses, massage, and topical antibiotics, with 76% of dacryocystoceles resolving after 6 days of medical management. Babies born with dacryocystoceles may have intranasal extension and develop respiratory distress after birth. Current recommendations include early probing at 4 to 6 months of age if symptoms persist.

### Mouth

The mouth should open at equal angles bilaterally. Unilateral facial nerve palsy is associated with an asymmetrical cry (Figure 94-6), inability to close the eye, flattening of the nasolabial fold, and drooping of the corner of the mouth on the affected side. When muscle activity of the tongue against the hard palate is limited or nonexistent during fetal life, the mandible does not develop fully, resulting in micrognathia. This anomaly occurs as part of the triad of retrognathia or micrognathia, glossoptosis, and airway obstruction in the Pierre Robin sequence. Babies with micrognathia can have respiratory distress, airway obstruction, and feeding difficulties. An important part of the mouth examination is inspection and palpation of the hard and soft palate and uvula for evidence of a cleft. A posterior cleft palate may be missed if complete inspection of the palate is not performed. Cleft lip and palate can be hereditary or associated with syndromes. A bifid uvula may be a sign of underlying submucous cleft palate.

**Figure 94-6** Asymmetrical crying facies.

Natal teeth are present at birth and are different from neonatal teeth, which erupt during the first post-natal month. Mobile natal or neonatal teeth should be assessed first for mobility. Only in the presence of one of the following 3 conditions should these teeth be removed: (1) the tooth is so loose that it needs to be removed to prevent aspiration, (2) the tooth is injuring the mother at breastfeeding, (3) the baby is injuring himself or herself when feeding. These are the specifics of extracting natal or neonatal teeth. Be aware that these might be the only primary teeth the baby has, so a radiograph is indicated to diagnose the presence of supernumerary teeth.

Ankyloglossia, commonly referred to as *tongue-tie*, is caused by a short frenulum on the underside of the tongue that prevents complete protrusion of the tongue. It is a common oral anomaly that can interfere with breastfeeding, speech articulation, and mechanical tasks. Macroglossia can be congenital or acquired; it can be localized when caused by a congenital hemangioma, or it can involve the entire tongue in such disorders as hypothyroidism, Beckwith-Weidemann syndrome, Pompe disease, and Down syndrome.

Mucocoeles are lesions of the oral mucosa that occur as a result of leakage of salivary mucin into the surrounding soft tissues, producing a granulomatous tissue response. Mucocoeles lack a true epithelial lining and are classified as pseudocysts. The most common location for a mucocoele is the lower lip. Clinically, mucocoeles are usually small, fluctuant, asymptomatic mucosal swellings that are benign and thought to occur in response to salivary gland trauma. Ranulae are benign sublingual cysts that may rupture with vigorous sucking. Epstein pearls are small, white inclusion cysts present at the junction of soft and hard palate. These cysts usually resolve spontaneously with sucking. Excessive drooling from the mouth can be normal, or it may be an early sign of esophageal obstruction or isolated neuromuscular swallowing difficulties. Esophageal obstruction can be easily diagnosed by the inability to pass the feeding tube to the stomach.

### Neck

A newborn should be able to turn the head to both sides of the shoulder. The rooting reflex can elicit this movement when the baby turns the head to the side when stimulated. Inability to turn the head should raise the concern about congenital torticollis. Persistent limitation of neck movement requires a referral for physical therapy evaluation. Webbing of the neck can be associated with Turner or Noonan syndrome. The examiner should inspect the clavicles for crepitus, mass, or tenderness, which is suggestive of a fracture. Newborns with a clavicular fracture exhibit limited movement of the arm on the affected side. The sternocleidomastoid muscles should be palpated for evidence of hematoma or fibroma, and the range of rotation of head to each side should be checked. The neck should be examined for the presence of thyroid enlargement and thyroglossal or brachial cleft cysts. A branchial cleft cyst is a developmental defect that occurs as a result of incomplete closure of the brachial plate between the cleft and the pouch. Cystic hygromas are multiloculated, benign cystic structures arising from

lymphatic channels that can occur anywhere in the body. A cystic hygroma is the most common neck mass, typically arising posterior to the sternocleidomastoid muscle. Thyroglossal duct cysts are caused by dilation of a remnant at the site where the primitive thyroid descended from its origin at the base of the tongue to its permanent location, low in the neck. Failure of subsequent closure and obliteration of this tract predisposes a newborn to thyroglossal cyst formation. The resulting neck mass moves during swallowing.

### Cardiovascular System

Examination of the cardiovascular system includes assessment of the heart's rate, rhythm, and position; the pulse volume; adequacy of perfusion; and other signs of cardiovascular compromise. The normal heart rate is 120 to 160 beats per minute in the alert newborn. Some babies, particularly those exposed to a suboptimal intrauterine environment, may have low resting heart rates when at rest and during sleep. Bradycardia in a neonate is defined as a heart rate less than 100 beats per minute. Infants born to mothers with systemic lupus erythematosus will exhibit symptoms of congenital heart block and a fixed heart rate. Tachycardia occurs when the newborn heart rate exceeds 170 beats per minute. A heart murmur on the first day of life is usually benign and reflects blood flow across a patent ductus arteriosus. (See Chapter 101, The Newborn With a Heart Murmur or Cyanosis.) Both femoral pulses should always be palpated and compared with the brachial pulses. Weak femoral pulses or decreased blood pressure measured in the lower extremities must be immediately evaluated for coarctation of aorta. Weak pulses may also indicate hypotension or other significant heart disease. Bounding femoral pulses may indicate hypertension or patent ductus arteriosus.

### Chest and Lungs

The normal respiratory rate for a newborn is 40 to 60 breaths per minute. Newborns, especially preterm babies, often exhibit periodic breathing, with cycles of 5- to 10-second respiratory pauses. This phenomenon is simply a reflection of the immature breathing center of the baby's brain. Apnea, the cessation of respiration for more than 20 seconds, is associated with bradycardia and color change and requires rapid assessment and intervention.

Newborns experiencing respiratory distress may exhibit tachypnea, nasal flaring, grunting, and intercostal retractions. Subcostal retractions occur as a result of a newborn's primary use of the diaphragm during respiration. (For a detailed discussion of respiratory disorders in the newborn, see Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn.) Asymmetry of the chest may signify tension pneumothorax, diaphragmatic hernia, skeletal disorder, and intrathoracic mass. A barrel-shaped chest suggests the presence of a pneumomediastinum (particularly in the newborn with a history of meconium staining), the need for positive pressure ventilation in the delivery room, or a newborn who exhibits respiratory distress.

Malformation of the rib cage may be seen with chondrodystrophies. Pectus excavatum is a congenital

depression of the sternum and is usually insignificant. Both male and female infants may have breast enlargement or may exhibit galactorrhea in the initial postnatal period. Widely spaced nipples (internipple distance greater than 25% of the chest circumference) can be associated with congenital disorders such as Turner syndrome.

Supernumerary (or accessory) nipple, also known as polythelia, is a congenital developmental abnormality that occurs most commonly over the anterior aspect of the trunk (Figure 94-7). Supernumerary nipples are found along the embryonic milk line that extends from the axilla to the pubic region. Supernumerary nipples can vary in their structure, ranging from a fully developed accessory breast, areola, or nipple to a minute, rudimentary hyperpigmented structure. Incidence of supernumerary nipple is 25 per 1,000 live births, with a higher prevalence for the left side and male infants.

### Abdomen

The newborn abdomen is soft and slightly protuberant. Diaphragmatic hernia is a defect in the diaphragm that allows the abdominal contents to move into the chest cavity, resulting in a scaphoid abdomen. Diastasis rectus is caused by separation between the left and the right side of the rectus abdominis muscle. Diastasis recti is a common, normal condition in newborns and occurs more frequently in premature and black babies. The abdominal musculature should be examined for evidence of laxity, which can be associated with gastrointestinal and genitourinary anomalies, such as are seen in infants with prune belly syndrome. The examiner should auscultate for the presence of bowel sounds. The presence of a bruit on auscultation over the liver indicates an arteriovenous malformation; if heard over the kidneys, then renal artery stenosis is suggested. The spleen is not usually palpable. The liver can be palpated 1 to 2 fingerbreadths below the right costal margin, and the lower pole of the left kidney may be felt in the pelvic gutter. Enlarged kidneys are the most frequent cause of an abdominal mass in newborns. Dilated veins are sometimes visible on the abdominal wall, indicating venous distention.

**Figure 94-7** Infant with rudimentary supernumerary nipple.

**UMBILICAL CORD.** The examiner needs to review the delivery history for notations regarding the umbilical cord length and abnormalities related to nuchal cord, cord wrapped around the infant's body, or other abnormalities such as knots in the cord. The average umbilical cord length is 55 to 61 cm, with 85% of cords measuring between 46 and 79 cm (18 and 31 inches). Six percent of umbilical cords are considered to be short (<35 cm), and 9% are long (>80 cm). The umbilical cord length is related to the degree of fetal movements: the greater the fetal movement, the longer the cord. The degree of fetal movement also correlates with the degree of twisting of the cord. Umbilical cord complications are more common with abnormal cord lengths. Longer cords are more susceptible to knotting, entanglement, and prolapse. True knots in an umbilical cord are rare, occurring in less than 1% of live births. Knots are more common in monoamniotic twins, infants with long cords, and pregnancies complicated by polyhydramnios. Wasted umbilical cords are observed in neonates with fetal growth restriction, whereas macrosomic neonates are more likely to have bulky cords. The diameter of the umbilical cord varies in relation to the quality of Wharton jelly and is an indicator of fetal nutritional status. Abnormal marginal and velamentous cord insertion into the placenta also increases the risk for fetal growth restriction and single umbilical artery.

If the cord is broad at the base, then the newborn should be checked for the presence of a small omphalocele before the cord is cut in the delivery room. An omphalocele is a congenital malformation in which variable amounts of abdominal contents protrude into the base of the umbilical cord. The intestines are covered only by a thin layer of tissue and can be easily seen. Gastroschisis is an abdominal wall defect that occurs when the anterior abdomen does not close properly, allowing the intestines to protrude outside the fetus. Unlike the omphalocele, the bowel is not covered by the membrane and is located to the right of the intact umbilicus.

An umbilical hernia is a small defect in the abdominal wall at the umbilicus. It is most often visible when a newborn cries or strains because the pressure pushes the abdominal contents or fluid through the defect, causing it to bulge. The size of the umbilical hernia is determined by palpating the opening in the abdominal muscle, not by the amount of skin protruding. Umbilical hernias are also more prevalent in black infants and typically resolve over the first years of life. Prune belly syndrome is caused by laxity of the abdominal musculature and is associated with gastrointestinal, genitourinary system, and lung hypoplasia. Edema, discharge, redness, or foul odor around the umbilical cord are signs of omphalitis.

**SINGLE UMBILICAL ARTERY.** The normal umbilical cord contains 2 arteries and 1 vein. An isolated single umbilical artery (SUA) occurs in up to 2% of all live-born infants. It may be detected antenatally or identified on examination of the newborn after birth. Prenatally, only two-thirds of the SUA will be identified sonographically. An SUA is thought to result from either aplasia or atrophy of the second umbilical artery or from persistence of the normally transient early embryonic SUA. Associated structural

or chromosomal anomalies are found in 27% of infants with an SUA, with renal malformations being the most common finding. SUA is seen more frequently in monoamniotic twins, and intrauterine growth restriction was observed in 15% to 18% of newborns with an SUA.

A newborn found to have an SUA should be thoroughly examined for dysmorphic features, abdominal masses, and the presence of heart disease. Postnatal screening for other malformations is warranted if additional abnormalities are present on examination or if prenatal evaluation identified other anomalies. In the absence of identified physical abnormalities on antenatal ultrasound screening, the available research suggests a low yield from investigations after delivery in infants without positive examination findings, suggesting the presence of other anomalies.

### Genitalia and Anus

**MALE.** Usually at birth the glans is completely covered by the foreskin. The foreskin should not be retracted until the child is 3 to 10 years of age. The skin on the underside of the penis may be tethered to the scrotum, called the chordae, and may or may not be associated with hypospadias. Hypospadias is a defect of the urethra in a male infant that involves an abnormally placed urethral meatus. Instead of opening at the tip of the glans, a hypospadiac urethra opens anywhere along a line running from the tip along the ventral aspect of the shaft to the junction of the penis (Figure 94-8). Infants with hypospadias should not undergo circumcision because the foreskin is often used during the surgical repair. Epispadias is an opening on the dorsal surface of the penis. A malpositioned meatus may be associated with urethral or kidney abnormalities and may result in poor urinary stream.

**Figure 94-8** Schematic of urethral orifice in hypospadias.

Penile length varies from 2.5 to 3.5 cm. The penis may appear short in an obese infant with suprapubic fat. A microphallus, or micropenis, should be suspected if the stretched penile length is less than 2 standard deviations below the mean for age; measurements of less than 2.5 cm in a term newborn male meet the definition of micropenis. The examiner should observe infants with micropenis (especially if other abnormalities associated with hypopituitarism are present) for evidence of metabolic derangements. Among neonates with pituitary dysfunction an early clinical sign is hypoglycemia. If hypoglycemia occurs, then glucose, insulin, growth hormone, and cortisol levels should be immediately obtained.

The scrotum is smooth or has a rugated appearance. Confirmation of descended testes is important for the infant with a bifid scrotum. If the testicles are not felt in the scrotum, then the inguinal canal should be palpated for the testicles. Black, Asian, and Hispanic infants can have darker scrotum (Figure 94-9). Pigmentation of scrotum can be a sign of congenital adrenal hyperplasia. Testicular size, noted as a volume, is 1 to 2 mL. Transillumination should be performed if the scrotum seems distended to determine whether a hydrocele is present. If the scrotum does not transilluminate, then the infant should be examined closely for a tumor or torsion.

Discoloration of the scrotum may be present in a neonate born after breech presentation or may be caused by testicular torsion or hematoma. Testicular torsion results in vascular compromise to the testes, and if blood flow is not restored in a timely fashion, testicular ischemia, infarction, and subsequent atrophy will occur. Prenatal testicular torsion is an in

**Figure 94-9** Full-term male genitalia. The scrotum of the term infant with descended testes will be pendulous with well-developed rugae. The scrotum of infants with deeper skin pigmentation (black, Native American, and nonwhite Hispanic infants) will appear darker than the rest of their skin.

utero event, and the torsion is generally detected at the initial newborn examination. The neonate does not demonstrate any clinical signs of distress, but on examination the testicle typically is enlarged, firm, and nontender with a discolored and fixed hemiscrotum. In rare cases, if the torsion occurred early in utero, the neonate may present with a firm, small testicle or even with an absent or nubbin testicle.

Cryptorchidism is common in the newborn infant, given that most undescended testicles are present at birth. (See Chapter 272, Hypospadias, Epispadias, and Cryptorchidism.) Three percent to 5% of term male infants are affected. Predisposing factors include prematurity, low birth weight, twin gestation, and first-trimester exposure to estrogen. Up to 30% of premature male newborns can be affected. Undescended testicles may be true undescended testicles, ectopic testicles, or retractile testicles. A newborn who seems phenotypically male but does not have palpable testes bilaterally should be considered to be a virilized female infant with congenital adrenal hyperplasia until proved otherwise. Congenital adrenal hyperplasia may rarely produce a normal male phenotype and is a life-threatening condition.

**FEMALE.** The labia can be swollen or ecchymotic after a breech delivery. In a term infant, the labia majora is enlarged and covers the labia minora, clitoris, urethral meatus, and external vaginal vault. Infants can have a creamy white to a slightly blood-tinged discharge 2 to 3 days after birth caused by maternal estrogen withdrawal. An enlarged Bartholin gland can appear as an imperforate hymen. Vaginal mucosal skin tags are a common finding and may extend beyond the rim of the hymen. They usually disappear within the first few weeks of life. Occasionally, small vesicles with no erythema may be clustered around the genitalia, and their surface is frequently broken. The hymen should be gently inspected to assess for the presence of an opening. An imperforate hymen can cause hydrometrocolpos, which usually appears as a bulging hymen, especially with crying.

Virilization of the genitalia may be difficult to identify; both labia need to be spread to ensure that no labioscrotal fusion is present, and the labia majora should be palpated to be sure that no gonads are present. Infants with ambiguous genitalia need a multidisciplinary workup before assigning the gender. Gender assignment should be delayed if the genitalia are incompletely developed or seem indeterminate. (See Chapter 243, Disorders of Sex Development.)

### Anus and Rectum

In female newborns, anal position index is the distance between the posterior fourchette and the anus divided by the distance from the coccyx to the fourchette—usually 0.44 cm ( $\pm 0.05$  cm). In male newborns it is the distance from the anus to the scrotum divided by the distance from the coccyx to the scrotum—usually 0.58 cm ( $\pm 0.06$  cm).

Measurement of the anal position index is helpful in identifying ectopic anus, which is mild mislocation of the anus often missed in the newborn exam; these patients present later in life with constipation. Anterior ectopic anus is different from imperforate anus with perineal fistula in that the anal opening is usually of normal size and only mildly misplaced.

Occasionally a large fistula may be mistaken for an anus. Fistulae may be located anterior or posterior to the anus and may connect to the bladder. An imperforate anus occurs in approximately 1 in 5,000 newborns. The rate is slightly higher among boys than girls, and it can occur as an isolated anomaly or in association with other abnormalities of the rectum and anus.

### Musculoskeletal System

**SPINE.** The newborn's spine should be examined with the infant in the prone position. Infants are often noted to have a nevus simplex (*stork bite*) at the nape of the neck that is insignificant and disappears with time. Asymmetry in the creases at the thigh or buttock may be evident in a neonate with developmental dysplasia of the hip. The examiner should palpate the spine to check the curvature; any midline defect on the dorsal surface can be an indication of spine anomalies. The examiner should assess for symmetrical motion of the major joints, including the shoulders, hips, knees, elbows, ankles, and wrists.

A pilonadal sinus (sacral dimple) may be present at the base of the spine between the buttocks. It is typically benign although, rarely, a true sinus tract associated with a meningocele may exist. Abnormal pigmentation, overlying hemangioma, pigmented nevus, or a hair tuft over the lower spine may be associated with vertebral anomalies (Figure 94-10). Lipomas are palpable masses that move with the skin. Spinal dysraphism is usually a midline defect, whereas a sacrococcygeal teratoma tends to be located lateral to the midline. The scapulae should also be palpated to check their size, symmetry, and location. A scapula that is smaller and higher in position on 1 side should alert the physician to Sprengel deformity.

**Figure 94-10** A hair tuft over the spine may be associated with vertebral anomalies.

**EXTREMITIES.** The physician should examine the palmar creases. Simian creases (single transverse creases) occur normally in 5% to 10% of the population, although the presence of a simian crease is highly associated with a chromosomal and congenital abnormality. The upper extremities should be examined thoroughly for evidence of any brachial plexus injury;

limb position, posture, symmetry, and range of motion should be assessed. Figure 94-11 provides a checklist for use in the assessment and follow-up care of an infant with a suspected brachial plexus injury.

**LIMB AND DIGIT ABNORMALITIES.** Congenital deformities affect 1% to 2% of all newborns, and 10% of these deformities involve the upper extremity. Congenital

**Figure 94-11** Suspected Brachial Plexus Injury (BPI): Evaluation and Management Form.

limb anomalies are classified according to the pattern of abnormal embryonic development. This includes the failure to form limb parts, failure of differentiation, duplication, overgrowth, undergrowth, congenital constriction band syndrome, and generalized skeletal abnormalities. Syndactyly (abnormal fusion of digits) or polydactyly (supernumerary or duplicated digits) and clinodactyly (radial deviation of the fifth digit) can be associated with syndromes. (See Chapter 96, Common Congenital Anomalies.) Polydactyly may be pre- (located on the radial aspect of the hand or tibial side of the foot) or post-axial (located on the ulnar side of the hand or fibular side of the foot). Post-axial polydactyly occurs at approximately twice the frequency as pre-axial polydactyly and varies by race. Post-axial polydactyly occurs more commonly than the other abnormalities, particularly among individuals of African descent, and is typically an isolated defect. In contrast, pre-axial polydactyly occurs more commonly in individuals of European descent and is frequently associated with other abnormalities or syndromes. The extra digit should be palpated for the presence of bony structures; often, the extra digit is attached to the hand by a thin stalk that can be easily ligated before the infant's discharge from the hospital. The inheritance pattern is most often autosomal dominant with incomplete penetrance, although recessive inheritance patterns have been identified. Phenotypic presentations of ulnar polydactyly range from a small skin appendage on the ulnar aspect of the hand to a fully formed ulnar digit. Syndactyly affects 1 per 1,000 live births and may occur sporadically or in families or in association with other abnormalities. Syndactyly is considered to be simple when skin alone is involved, complex when there is bone connection, complete when the web involvement includes the nail, incomplete or partial when the nail is not involved but when the web depth is not normal, and complicated when there are multiple tissue abnormalities. The newborn with apparent syndactyly should be closely assessed for evidence of constriction band (amniotic band) sequence. The nails should also be examined for abnormalities.

Each year approximately 4 of every 10,000 babies will have upper limb reductions, and approximately 2 of every 10,000 babies will have lower limb reductions. Some of these babies will have both upper and lower limb reduction defects. Limb deficiencies have been associated with teratogenic exposures during pregnancy, such as thalidomide and misoprostol, and reported to rarely occur following prenatal diagnostic procedure (chorionic villus sampling, amniocentesis). Infants exposed early in pregnancy to misoprostol or chorionic villus sampling have a small, but higher than the general population, risk for developing a vascular disruption that results in asymmetrical digit loss, constriction rings, and syndactyly. Among the spectrum of radial limb deficiencies that may be seen in the newborn is an absent or hypoplastic thumb. Radial deficiencies are often associated with other anomalies. Infants with limb deficiencies should be referred to an orthopedic or plastic surgeon for evaluation and management planning.

The presence of a dimple on the anterior leg suggests the presence of an underlying bony abnormality

and warrants further evaluation. Alignment of the legs from the hips to the toes should be assessed to identify rotational misalignment. The number and appearance of the newborn's toes should be assessed for the presence of polydactyly, syndactyly, hypoplasia, overlap, and abnormal alignment. The extremities should also be observed for symmetry in limb size and muscle bulk. Genu recurvatum is a congenital anomaly of the lower limb, with hyperextension of the knees (Figure 94-12). Genu recurvatum can be associated with congenital dislocation of hips, cerebral palsy, joint hypermobility, or clubfoot. Dislocation of the patella should be suspected if lateral displacement of the patella and limited knee motion are present.

A healthy newborn's foot is usually supinated and adducted at the forefoot, with increase in the distance between the first and the second toe. The range of motion of the ankles and subtalar joints should be examined. Metatarsus adductus is typically a positional deformation that occurs in varying degrees of severity and is frequently correctable with passive range-of-motion exercises. Metatarsus adductus may occur as a structural abnormality, with a fixed position that does not allow abduction of the foot beyond a neutral position. Talipes equinovarus (clubfoot) is inward with medial rotation of the foot, mild calf atrophy, and hypoplasia of the foot, tibia, and fibula. Another component of clubfoot is cavus midfoot deformity. Limited dorsiflexion or a fixed equinus position of the foot occurs with congenital foot anomalies. Orthopedic evaluation and follow-up are required for a newborn with an equinovarus deformity.

All newborns should be examined for developmental dysplasia of the hip. A positive Galeazzi sign is a functional leg-length discrepancy when the knees and hips are flexed. Also, the hip examination should be done carefully in a relaxed baby—gently and without any force (Figure 94-13). The Barlow test dislocates an unstable hip. With the newborn placed in a supine position and the hips in flexion, the hips are grasped and adducted, with simultaneous downward pressure applied. The Ortolani test is performed to assess the relocation of a dislocated hip. In this maneuver, the hip and knee are flexed while the thigh is grasped and the pelvis is stabilized by the examiner's other hand. The thigh is abducted as pressure is applied on the greater trochanter to reduce a dislocated hip. On dislocation of the femoral head against the acetabulum, a *clunk* is felt. Benign clicks are more commonly observed, caused by movement of the ligamentum teres in the acetabulum or a tendon such as the iliopsoas popping over the femur. Any hip instability should result in an orthopedic referral. Breech position and a family history of developmental hip dislocation are major risk factors for hip instability.

### Neurologic Examination

The neurologic assessment includes examining the motor system, reflexes, sensory system, and cranial nerves (Table 94-4). A full-term newborn's posture in a quiet state is typically abducted, with partial flexion

**Figure 94-12** Genu recurvatum.

**Figure 94-13** Asymmetrical thigh creases in developmental dysplasia of the hip.

**Table 94-4**

**Neonatal Neurologic Evaluation**

TEST	TECHNIQUE	NORMAL FOR TERM	DEVIANT FOR TERM
Resting posture	Observe unswaddled infant without contact in quiet awake, quiet active, or light sleep states	Moderate flexion of 4 limbs, held off bed  Equal side to side and upper to lower if head is in midline Extension of neck in face presentation or legs in breech	Constant tight flexion  Full extension, flaccid or forced Knees abducted to bed (ie, frog leg)  Elbows flexed with dorsum of hands on bed Tight, persistent fisting ATNR persistent 30 sec Strong lateral preference
State	Deep sleep to light sleep Awake, light peripheral movements Awake, large movements, not crying Awake, crying	Moves from 1 to the other with appropriate stimuli Self-calms  Modulated cry with expression	Is difficult to move from 1 to the other Stays too alert or cries without physical reason Does not come to fully awake state Weak or monotonous cry
Motor activity	Observe throughout physical examination	Appropriate for state of alertness  Symmetrical, fairly smooth Expressive face with yawn or cry	Bicycling, swatting without stimulus Asymmetrical, weak Jittery while sucking Flat facial expression
Phasic (ie, passive)	Measure resistance to extension (limb recoil)	Response appropriate for gestational age	Resists too much or too little

*Continued*

**Table 94-4 Neonatal Neurologic Evaluation—cont'd**

TEST	TECHNIQUE	NORMAL FOR TERM	DEVIANT FOR TERM
Tone: resistance to movement	Scarf, heel to ear	Patellar is only reflex reliably present at birth	Asymmetry
Tendon reflexes	Test patellar reflex with head midline		Sustained clonus
Postural (ie, active)	Pull to sitting while grasping infant's hands	Infant pulls back with flexion at elbows, knees, and ankles	Asymmetry in pulling back
Tone: resistance to gravity		Head comes with body with minimal lag and falls forward when sitting is obtained	No resistance, full head lag
Traction response			Pull to stand instead Head does not fall forward as infant goes past upright
Upright suspension	Suspend infant facing examiner with both hands in axillae	Infant supports self then yields slowly	Infant falls through immediately
		Holds head erect, flexes hips, knees, and ankles Eyes open	Legs extend, eyes fail to open Infant fails to relax and fall through after 1 min
Ventral suspension	Hold infant under chest and suspend in prone position	Flexes arms, extends neck, holds back straight	Hangs limply or excessively rigidly
	Galant: stroke adjacent to spine	Curves toward side of stimulus	Asymmetrical incurving
	Landau: stroke caudocephalad along spine	Extends back, lifts head and pelvis, micturates	Weak or absent response
Positive support	Hold infant to support trunk with feet touching firm, flat surface	Infant extends hips to bear his or her own weight and relaxes after 1 min	Infant fails to bear weight or extends too much or too long
Integrated reflexes	Hold infant in supine position	Spreading: arms abduct and extend; hands open	Unequal laterality
Moro reflex	Support head and neck with hand; allow head to drop while still supporting it	Hugging: arms adduct and flex; hands close	Asymmetry; exaggeration with disorganization in state
Tonic neck reflex	Infant in supine, neutral position; turn head to 1 side; repeat with opposite side	Mental extension, occipital flexion primarily of arms; does not remain in position for >30 sec	Exaggerated response and stays in position >30 sec
Withdrawal reflex	Painful stimulus to 1 foot	Withdrawal of stimulated foot; variable extension of opposite leg	Absence of flexion in stimulated leg

at the hips and knees; the arms are adducted and flexed at the elbow. Newborns have their fists loosely clenched with the thumb on the palm. Neurologic maturity is evaluated as part of gestational age assessment, as described previously. The posture, state regulation and behavior, muscle tone, responses, and reflexes provide valuable information about the newborn's adaptation to extrauterine life and may provide clues to the newborn's intrauterine experiences. Signs on neurologic examination that warrant further evaluation include fisting or abnormal posturing of the trunk, hands, or feet; excessive tremulousness; clonus or atypical movements suggestive of seizure activity; abnormal eye movements; and a decreased or absent response to

visual or auditory stimuli. (Refer to Chapter 107, The Newborn With Neurologic Findings, for a more detailed discussion.)

## Chapter 95

## NEONATAL SKIN

Julian Trevino, MD; Amy Yuntzu-Yen Chen, MD;  
Catherine Ulman, MD

By the end of the third trimester of pregnancy, the skin structure and composition of a fetus are similar to that of an adult. The skin contains a mature lipid bilayer, substantial subcutaneous fat, and differentiated epidermal layers. The primary functions of neonatal skin are mechanical protection, maintenance of thermoregulation, immune surveillance, and prevention of insensible loss of body fluids. Skin of premature infants is thinner and much less effective than skin of term infants in these functions.

### SKIN CARE OF NEWBORNS

The developmentally immature skin barrier in premature infants can result in increased transepidermal water loss, difficulties in thermoregulation, higher risk for infection, increased absorption of environmental toxins, and predisposition to injury from minor skin trauma. Hand washing by caregivers is the most effective way to prevent skin colonization and nosocomial infection. Mild, alkaline to neutral pH cleanser (eg, chlorhexidine) is suggested for hand decontamination.

Premature infants are at marked risk for percutaneous toxicity compared with term infants. A conservative approach to applying topical products to the skin of preterm infants must be undertaken. Only essential products should be used, and these should be washed off once their purpose has been achieved.

Sterilization of the skin before invasive procedures are performed on the neonate is assumed to eliminate pathogens from the local site and reduce the risk for subsequent bacteremia and sepsis. Chlorhexidine seems to be the safest and most effective agent for local skin sterilization. Chlorhexidine has also been found to be a safe and effective agent for reducing bacterial colonization of the umbilical cord stump.

Bathing of neonates should be delayed until vital signs have been stable for several hours. Excessive vernix is best left on the skin. For preterm infants, particularly those with compromised barriers, water-only nonimmersion bathing up to 3 times a week is suggested for the initial 2 to 4 weeks of life. Rubbing or scrubbing the skin should be avoided. If soap is required, then only mild, neutral-pH soaps without additives should be used in heavily soiled areas; these soaps should be promptly rinsed from the skin.

Although treatment with emollient theoretically promotes the integrity and function of the stratum corneum, studies have revealed a trend toward increased risk for bacterial infection in infants prophylactically treated with emollient. Based on these studies, topical ointment should not be used routinely in preterm infants.

Neonatal skin, especially that of preterm neonates, is highly susceptible to injury. Routine precautions such as care in handling, minimal use of skin adhesives, hydrogel-based chest leads, and masks should be routinely followed.

## PIGMENTARY BIRTHMARKS

### Congenital Disorders of Hypopigmentation and Depigmentation

*Nevus depigmentosus* refers to macular hypopigmentation that is present at birth and stable throughout the lifetime (Figure 95-1). Lesions are usually unilateral and block- or flag-shaped. Hypopigmented linear or segmental macules are seen in patients with hypomelanosis of Ito. Lesions can be present at birth, or they can develop during infancy or childhood. The spectrum of this disorder ranges from those with only cutaneous involvement (most common) to those in which cutaneous lesions are associated with ocular, musculoskeletal, or neurologic disorders. This disorder is hypothesized to be the result of chromosomal mosaicism.

Hypomelanotic macules are generally the first cutaneous clue to the diagnosis of tuberous sclerosis. These lesions are often present at birth, although in individuals with light skin types, a Wood lamp may be needed to demonstrate their presence. The most common hypopigmented lesion is an elliptical or ash-leaf macule. Less commonly, guttate hypopigmented macules of the pretibial areas or segmental hypopigmented lesions may be present. As patients age, additional cutaneous manifestations of tuberous sclerosis (facial angiofibromas, periungual fibromas, and connective tissue nevi) often become evident.

*Piebaldism* is an autosomal dominant disorder characterized by depigmented patches of skin on the forehead, anterior trunk, and extremities. Forehead lesions may be associated with a white forelock (poliosis). In rare cases, patients with piebaldism can have associated problems, including intellectual

disability. This disorder results from mutations in the *KIT* gene.

### Hyperpigmented Lesions

Congenital hyperpigmented lesions are the result of accumulation of melanin in melanocytes or keratinocytes, melanin incontinence, proliferation of nevus cells in the epidermis or dermis, or thickening of the stratum corneum.

Proliferation of dermal melanocytes produces brown, blue-gray, or blue-black patches. Such lesions are termed congenital dermal melanosis. Mongolian spot is an outdated term used to describe congenital dermal melanosis in the sacrogluteal area. Less commonly, these spots can be located on the dorsal trunk, extremities, and scalp. These lesions are the most common birthmarks in patients with highly pigmented skin, being present at birth in 85% of Asians, 96% of blacks, and 46% of Hispanics. Congenital dermal melanosis typically increases in size during the first year and subsequently fades during childhood. *Nevus of Ota* is a blue-gray patch in the distribution of the ophthalmic or maxillary branch of the trigeminal nerve. This patch can be associated with glaucoma, and rare cases of ocular melanoma have been found in these patients. *Nevus of Ito* is a unilateral hyperpigmented patch over the deltoid or scapula. The nevus of Ota and nevus of Ito do not involute with time. The pathogenesis of dermal melanocytosis is thought to be caused by a defect in melanocyte migration from the neural crest to the skin.

One to 3 *café-au-lait macules* (CALMs) are present in 10% to 28% of the general population. More than 3 and particularly more than 6 CALMs may indicate an underlying disorder. Neurofibromatosis type 1 is the most common associated disorder. Large, linear, or segmental CALMs are seen in McCune-Albright syndrome. Additional features characteristic of McCune-Albright syndrome are polyostotic fibrous dysplasia and endocrine abnormalities, which unusually exhibit as precocious puberty.

*Congenital melanocytic nevi* (moles) are classified as small (<1.5 cm diameter), medium (1.5–19.9 cm diameter), and large (>20 cm diameter) (Figure 95-2). Although small congenital nevi occur in up to 1% of infants, large congenital nevi are rare, occurring in 1 in 20,000 infants. In addition to the psychosocial aspects associated with having large nevi, complications include neurocutaneous melanosis, limb hypoplasia, cutaneous melanoma (lifetime risk of 6%–8% in those with large congenital nevi), and extracutaneous melanoma. Congenital nevi larger than 40 to 60 cm are at highest risk for the previously mentioned complications. Furthermore, large congenital nevi on the trunk are at greater risk for developing into cutaneous melanoma, and patients with numerous satellite nevi are at highest risk for developing neurocutaneous melanosis. More than 70% of cases of cutaneous melanoma in patients with large congenital melanocytic nevi are diagnosed before the age of 10 years. Neurocutaneous melanosis can initially be asymptomatic. Magnetic resonance imaging (MRI) is the modality of choice for identifying neurocutaneous melanosis. However, the necessity for brain imaging in asymptomatic patients

**Figure 95-1** Nevus depigmentosus. (Copyright © Johnell Kolve, Dermatlas; www.dermatlas.org.)

remains controversial. In symptomatic patients, imaging with MRI is important in addition to serial clinical neurologic examination. In patients with large congenital melanocytic lesions located over the midline lumbosacral area, MRI can be used to rule out tethered spinal cord. Management of patients with large congenital nevi needs to be individualized and often requires multidisciplinary care. Partial or complete excision is sometimes suggested for large congenital nevi. Although prophylactic surgical intervention theoretically reduces the risk for malignant transformation and improves cosmesis, it is important to note that critical review of the current literature is not able to answer whether surgical intervention reduces the true risk for cutaneous melanoma. Surgical treatment of large congenital nevi does not affect the risk for neurocutaneous melanosis. Small- and medium-sized congenital nevi should be followed with serial examinations and removed if they manifest clinical changes that cause concern.

*Nevoid hypermelanosis* is macular hyperpigmentation in a segmental or whorled pattern. This usually presents in the first few weeks of life and spreads until the end of the second year. Nevoid hypermelanosis can be an isolated cutaneous condition or part of a genetic disease, which is the result of cutaneous mosaicism.

#### WHEN TO REFER

- Large congenital nevi
- Small or medium congenital nevus with concerning clinical features (ie, asymmetry, border irregularity, color variegation)

### VASCULAR ANOMALIES

Vascular anomalies can be classified as either tumors or vascular malformations. *Infantile hemangiomas* (IH) are the most common vascular tumors found in newborns and infants, are rarely present at birth, and usually develop at a few days to a few weeks of life (Figure 95-3).

**Figure 95-2** Large congenital nevus.

These benign proliferations of vascular endothelium are characterized by a predictable growth pattern and a tendency toward spontaneous involution. *Vascular malformations* are congenital lesions composed of mature vessels (arterial, venous, capillary, lymphatic, or combinations). Malformations generally do not spontaneously involute. Examples of vascular malformations include nevus simplex (salmon patch) and nevus flammeus (port wine stain).

Infantile hemangiomas develop in 1.1% to 2.6% of newborns; incidence figures at the end of 1 year are 10% to 12% of white infants. The prevalence is highest in low-birth-weight, white, female infants. Many hemangiomas are heralded by precursor lesions—well-demarcated red macules or telangiectasia, often surrounded by an area of pallor. Fully developed hemangiomas range from soft, bright-red lobulated plaques (*superficial hemangiomas*, formerly known as strawberry hemangiomas) to purplish-blue, poorly defined, compressible subcutaneous nodules or tumors (*deep hemangiomas*, formerly known as cavernous hemangiomas). Most IH have both a superficial and deep component. Most IH present as single round or oval papules or plaques from a few millimeters to a few centimeters in size, referred to as *focal IH*. Fifteen percent to 30% of affected infants have more than 1 focal IH, referred to as *multifocal IH*. Large IH, which account for fewer than 5% of IH, often present as unusual block-like patterns, referred to as segmental IH.

Most IH undergo a proliferative growth phase lasting typically 2 to 4 months, followed by a period of stabilization, and finally an involutional phase. Most IH reach maximal size by 4 months and begin to regress during the second half of the first year of life. Some IH, particularly deep IH, may have a prolonged growth phase that extends to the first birthday or a few months beyond.

**Figure 95-3** Hemangioma of infancy.

Involuting hemangiomas are characterized by loss of bright red color, acquisition of a grayish hue particularly in the center, and loss of volume. Although considerable variation exists in involution, generally 50% of hemangiomas have completely involuted by age 5 years; approximately 10% involute each year thereafter such that, by age 9, approximately 90% have undergone complete involution. Up to 50% of affected patients will have residual skin changes, most commonly telangiectasias, pallor, or redundant atrophic skin.

Management for most IH is watchful waiting and parental education. Parents should be advised to notify the physician if any of the following occur: sudden, rapid growth of the hemangioma; development of a hard, woody texture; prolonged bleeding from the hemangioma; or development of erosions, ulcerations, or crusts. Hemangiomas that may be associated with complications include large IH of the face or beard area, perioral hemangiomas, segmental hemangiomas, and hemangiomas involving the midline spine. Unfortunately, small, subtle IH may grow quickly and suddenly after discharge from the nursery and before the follow-up visit with the primary care pediatrician, so IH in strategic areas often require parent counseling in the nursery or early referral for consultation during the first few weeks of life. PHACE and LUMBAR syndrome should be considered in infants with large segmental hemangiomas. PHACE syndrome describes the association between large (>5 cm in diameter) facial hemangiomas with structural abnormalities of the brain, cerebral vasculature, eyes, sternum, and/or cardiac vasculature and large vessels arising from the aorta. Infants with suspected PHACE syndrome should have brain MRI and magnetic resonance angiography, cardiovascular imaging, and an eye examination. LUMBAR syndrome describes the association between lower body hemangiomas and urogenital anomalies, ulceration, myelopathy, bony deformities, anorectal malformations, arterial anomalies, and renal anomalies. Initial evaluation of infants younger than 3 months with a hemangioma on the lower half of the body should include color Doppler ultrasound imaging of the spine, abdomen, and pelvis. The recommendations for additional imaging vary based on the exact anatomic location of the hemangioma. Additionally, infants with multiple hemangiomas may require evaluation to exclude the presence of internal hemangiomatosis (especially hepatic). Magnetic resonance imaging, therapeutic intervention with systemic corticosteroid therapy, laser treatment, or any combination of these modalities may be necessary in severe cases. Since its initial report as a successful treatment in steroid-refractory hemangiomas, there have been multiple successful case series documenting the effectiveness of off-label propranolol, a nonselective beta blocker, in the treatment of both cutaneous and visceral IH. In May 2015, a special formulation of propranolol, hemanageol, was approved by the FDA for the treatment of IH at a dose of 3 mg/kg/day in 2 divided doses. In North America many physicians use a lower dose of 2 mg/kg/day in 2 or 3 divided doses. In general, propranolol is well tolerated. However, serious adverse effects such as bradycardia, hypoglycemia, hypotension, and bronchospasm have rarely been reported in those treated

with propranolol. Caution should therefore be exercised when administering propranolol for IH.

### WHEN TO REFER

- Large IH of the face or beard area
- Periorificial IH (especially perioral and periocular IH)
- Lumbosacral IH
- Ulcerated IH
- IH at risk for ulceration in the diaper area and other skin creases
- Multiple hemangiomas
- Segmental hemangiomas
- Disfiguring IH
- IH in strategic areas during the first few days of life (should be monitored closely during the first 2 weeks of life)

### VASCULAR MALFORMATIONS

*Nevus simplex* (salmon patch) is a capillary vascular malformation seen in approximately 40% to 80% of infants (Figure 95-4). These lesions are pink, blanch completely, have indistinct borders, and usually darken in color with crying, vigorous activity, or changes in ambient temperature. Common locations are the glabella, upper eyelids, and nape of the neck. The lesion is presumed to be composed of ectatic dermal capillaries representing persistent fetal vessels. Virtually all eyelid lesions will involute; a small number of glabellar lesions will persist. Nuchal lesions generally lighten during the first or second year, but careful observation will usually reveal some subtle lesions into adulthood. Persistent salmon patches will generally respond to treatment with the pulsed dye laser if necessary in psychosocially important areas.

*Port wine stain* (nevus flammeus) is a less common capillary malformation that occurs in 0.3% of newborns (Figure 95-5). The initial manifestation is a red to purple-red discrete patch with irregular borders,

**Figure 95-4** Glabellar salmon patch and nevus sebaceous.

usually unilateral in distribution. If left untreated, port wine stains will become purple and nodular in adulthood. It is a permanent mark and has no tendency toward involution. The most common site is the face with 50% involving the head and neck. A port wine stain represents a malformation of mature capillaries of the upper dermis. Although a port wine stain can occur as an isolated abnormality, some are associated with serious extracutaneous findings. Sturge-Weber syndrome (SWS) is characterized by a port wine stain in the trigeminal distribution in association with cerebral calcifications, glaucoma, seizures, and mental retardation. A recent study shows that the pattern may actually follow embryologic developmental patches rather than a trigeminal pattern and the GNAQ genetic mutation was identified as a trigger of SWS and a marker of somatic genetic mosaicism. Interestingly, the same mutation was identified in patients with isolated port wine stains. Port wine stain of an extremity, venous varicosities, and hypertrophy of soft tissues and bones are seen in Klippel-Trénaunay syndrome. The triad of findings in Klippel-Trénaunay syndrome plus the presence of an arteriovenous malformation constitutes Parkes-Weber syndrome (associated with RASA1 genetic mosaicism). Cobb syndrome is characterized by a port wine stain in a dermatomal distribution, a vascular malformation of the corresponding segments of the spinal cord, and neurologic manifestations of cord compression. Port wine stains, especially facial lesions, generally improve with laser treatment. If the distribution of the port wine stain and attendant findings suggest any of the aforementioned syndromes, then further evaluation, including MRI and consultation with a neurologist or an ophthalmologist (or both), is necessary for management.

### WHEN TO REFER

- Port wine stain involving the forehead, scalp, temple, or eyelids
- Large port wine stain of an extremity or overlying the midline
- Since port wine stains respond better to treatment early in life, any lesion in a strategically important area should be referred for evaluation shortly after birth

**Figure 95-5** Extensive vascular malformation.

## HAMARTOMAS AND MISCELLANEOUS LESIONS

*Hamartomas* are benign growths consisting of an excess amount of tissue (eg, smooth muscle, sebaceous glands) to that normally found in the location. They are usually not cancerous or hyperproliferative.

*Epidermal nevus* is a benign epidermal hamartoma that usually exhibits at birth or in early childhood (Figure 95-6). It is usually an isolated, small, hyperpigmented, slightly verrucous lesion, but it can be linear or extensive. Rarely, extensive epidermal nevi may be associated with skeletal, neurologic, cardiovascular, and ocular abnormalities (epidermal nevus syndrome). A biopsy is often performed to exclude the possibility of epidermolytic hyperkeratosis, which is a more severe skin condition that may be passed to offspring of affected patients. In rare instances, malignant proliferation has been reported. Treatment is not necessary, but options for symptomatic or cosmetically disfiguring lesions include destructive measures such as excision, cryotherapy, laser ablation, or electrosurgery.

*Nevus sebaceous* is a benign sebaceous hamartoma that manifests at birth or early childhood. It starts as a flesh-colored to yellow smooth plaque found mostly on the face and scalp. Associated alopecia is a common feature of scalp lesions. During and after puberty, the nevus enlarges and becomes more verrucous, corresponding to maturation of sebaceous glands. Benign and malignant neoplasms (including basal cell carcinomas) may develop within these lesions. Although some studies doubt the need for prophylactic excision of nevus sebaceous, authors of a 2009 review recommend that all nevi sebaceous should be excised because of the real (although low) risk for malignant transformation and concern of cosmesis. In their study, youth and the absence of clinical changes within the lesion also do not guarantee benignity. The timing of excision is based on risk of anesthesia, symptoms, and patient's medical history. It is best determined between the patient, parents, and surgeon.

*Smooth muscle hamartoma* is a congenital, skin-colored to hyperpigmented plaque that is present mostly on the trunk and proximal extremities (Figure 95-7). Hypertrichosis is a common finding. This lesion is

**Figure 95-6** Epidermal nevus.

benign; removal is indicated if it is symptomatic or for cosmetic reasons.

### DEVELOPMENTAL ANOMALIES

Developmental anomalies result from faulty morphogenesis at some point during embryonic development. These anomalies can affect any organ system, including the skin. Cutaneous defects may be an isolated, incidental finding or associated with other, possibly severe or life-threatening, abnormalities. They are also potential indicators of underlying defects or a manifesting feature of a syndrome.

*Branchial cleft cysts* present on the preauricular area, mandible, or lateral neck anterior to the sternocleidomastoid muscle during early childhood or adolescence. These cysts result from incomplete resolution of the second and third branchial clefts. Fistula or sinus formation is a common complication and must be delineated with an MRI or computed tomographic scan. These cysts must be differentiated from enlarged lymph nodes and thyroglossal duct cysts (remnants of the thyroglossal duct, which are located on the midline neck and often move with swallowing).

*Aplasia cutis congenita* is a congenital absence of skin that occurs most commonly on the vertex of the scalp but can be found anywhere (Figure 95-8). The lesion appears as a punched-out ulceration (that heals as a scar), or as a scar. Within the scar, no hair or appendages are present. The lesion is usually isolated, but multiple areas may be present. The lesion may involve deeper structures (absence of subcutaneous tissue or bony defects) or be associated with other congenital anomalies (neurologic, skeletal, gastrointestinal) or disorders (trisomy 13). Management involves routine wound care and prevention of infection. Once healed, no further care is necessary, but surgical excision is an option for improved cosmesis. For medicolegal reasons, the physician should recognize aplasia cutis congenita as an intrauterine event

**Figure 95-7** Smooth muscle hamartoma.

that is not related to birth trauma, electrode monitors, or forceps delivery.

The skin and the nervous system are both derived from the ectoderm. Therefore any midline lesion along the posterior axial skeleton can potentially indicate an underlying spinal abnormality and a need for further evaluation. Some common cutaneous posterior midline lesions suggestive of an underlying spinal defect include congenital nevi, vascular malformations, hemangiomas, hair tufts, lipomas, skin tags, dimples above the gluteal cleft, and subcutaneous nodules. An ultrasound (if within first few months) or MRI is necessary to assess for the presence of underlying spinal disease.

*Dermoid cysts* result from trapped ectodermal-derived tissue along embryonic fusion planes. These cysts appear as subcutaneous nodules mostly on the nose or around the eyes, especially near lateral eyebrows (Figure 95-9). A small percentage of midline nasal dermoid cysts will have intracranial involvement. Such lesions require imaging before they are excised.

*Nasal gliomas* represent ectopic neuroectoderm that was sequestered during bony fusion. No intracranial connection is found. Nasal gliomas exhibit as firm,

**Figure 95-8** Aplasia cutis congenita.

**Figure 95-9** Dermoid cyst of lateral eyebrow.

red, telangiectatic dermal nodules located on the nasal root. Less commonly, they can be located intranasally, causing distortion of the nose and obstruction. MRI is the imaging modality of choice.

*Cephalocele* is a generic term referring to herniation of any intracranial tissue through a skull defect resulting from faulty closure. Thus all cephaloceles have an intracranial connection. The most common cephaloceles are meningoceles (meninges only) and encephaloceles (meninges and brain). Most cephaloceles occur along the midline of the occiput or vertex. These appear as a soft, bluish, pulsatile nodule and rarely can be confused for deep hemangiomas or vascular malformations. If a cephalocele is clinically suspected, imaging must be done to define the extent of the tumor. Repair, often requiring collaboration between otolaryngology and neurosurgery, is indicated.

*Accessory tragi* are common anomalies that result from an extra tubercle or remnant of the first branchial arch. These anomalies are most often present in the preauricular area, but they can be seen on the cheek and lateral neck. Accessory tragi are usually an isolated defect, but they can be associated with cleft lip or cleft palate or with several syndromes. The infant must be assessed for other dysmorphic features, and the newborn hearing screen is important for evaluating potential hearing loss.

*Ear pits* are a common congenital defect resulting from defective embryonic fusion of the tubercles of the first 2 branchial arches. Cyst formation and infection are common complications. Rarely, ear pits are associated with hearing loss, renal abnormalities, and several syndromes.

*Supernumerary digits* (postaxial polydactyly) are soft tissue duplications that produce a papule or nodule, most often on the ulnar aspect of the fifth digit. No bone development is present. These are usually isolated anomalies without systemic associations. Supernumerary digits of the hand are a common isolated finding in black children, occurring with a frequency approximately 10 times that of white children and are seen more often in boys. Transmission is presumed to be autosomal dominant. In contrast, when seen in white children, supernumerary digits are more commonly found in association with a syndrome and autosomal recessive inheritance. Treatment of supernumerary digits consists of surgical excision.

*Accessory nipple* results from persistence of nipple or areola, or both, anywhere along the embryonic milk line (anterior axillary fold to medial upper thigh). These lesions are usually asymptomatic and may be single, multiple, unilateral, or bilateral. They are light brown and persist throughout life. Routine examination is essential because individuals with associated breast tissue have a similar risk for malignant transformation as with normal breast tissue. No treatment is necessary.

## VESICULOPUSTULAR DISEASES OF THE NEWBORN

*Erythema toxicum neonatorum* is a benign disorder occurring in 20% to 60% of term newborns and 5% of preterm neonates. Characteristically, the eruption begins during the second 24 hours of life; it is rarely present at birth. However, this eruption may begin

anytime from birth to 2 weeks of age and typically lasts several days to several weeks. A polymorphous eruption is present, consisting of erythematous macules, papules, pustules, and wheals. Lesions are most commonly found on the face, trunk, proximal arms, and buttocks. The palms and soles are usually not involved. The cause is unknown. The diagnosis is usually based on the clinical appearance of the rash in an otherwise healthy term newborn. In cases in which the diagnosis is in doubt, scrapings of pustules stained with Wright stain will reveal large numbers of eosinophils. Fifteen percent of cases are accompanied by peripheral eosinophilia. This disorder is self-limited and requires no treatment; parents should be reassured about the benign and noninfectious nature of this condition.

*Transient neonatal pustular melanosis* is a benign condition occurring in 0.2% to 4% of term babies and is more commonly seen in black newborns. Boys and girls are equally affected. Lesions are present at birth; new lesions do not usually appear after birth. The eruption generally resolves in 24 to 48 hours. Pustules, vesicles, or pigmented macules with or without a surrounding collarette of scale are present. The eruption typically affects the chin, neck, upper back, buttocks, abdomen, thighs, palms, and soles. The cause is unknown. This diagnosis is usually based on the time of onset, clinical appearance, and absence of other findings. Gram stain of pustules demonstrates neutrophils, rare eosinophils, and an absence of bacteria. No treatment is necessary; however, hyperpigmented macules may last for several weeks to months before resolving.

*Miliaria* are a common finding in neonates and infants. In warm climates, they may be present in up to 15% of newborns. Two types of miliaria commonly occur during the newborn period—*miliaria rubra* (known as *prickly heat*) and *miliaria crystallina*—with the former being more common. Incidence is equal among the sexes and races. Both types of miliaria can occur within the first weeks of life and can persist from hours to days. Vesicles, pustules, or papules occur in crops on the face, trunk, and intertriginous areas. Miliaria arise as a result of obstruction within the eccrine duct, followed by rupture of the duct and leakage of eccrine sweat into the skin. Precipitating factors include excessive warming in an incubator, fever, occlusive dressings, or dressing in inappropriately warm clothing. The diagnosis is usually based on lesion location, time of onset, and history of excessive warming. Miliaria usually resolve spontaneously. Providing cool baths and avoiding excessive warming can prevent recurrences.

*Eosinophilic pustular folliculitis* has been reported in neonates. Recurrent crops of white to yellow pustules occur on the scalp and forehead. Lesions crust within 2 to 3 days of onset and resolve without scarring. The course can be months to years in duration. The cause is unknown. The strong association with HIV seen in adults is not observed in neonates, although associated immunodeficiency has been reported. Multiple eosinophils are present on Giemsa stain of a lesion. Topical corticosteroids, erythromycin, or both have been reported to be effective treatments.

*Acropustulosis of infancy* is a chronic, recurrent eruption of vesicles and pustules occurring on the hands and feet. The onset is usually hours after birth, but it can occur anytime during the first year of life.

Lesions last 5 to 10 days; however, crops can appear every 2 to 4 weeks for 2 to 3 years in persistent cases. Erythematous papules rapidly progress to intensely pruritic vesicles or pustules (or both) on the hands, feet, ankles, and wrists, and occasionally on the chest, back, and abdomen. The cause is unknown. An association with scabies is suspected because both have similar clinical presentations. Scabies preparations in acropustulosis will be negative. Gram stain reveals numerous neutrophils and occasional eosinophils. The disease usually spontaneously remits within 1 to 2 years. Symptomatic treatment includes topical corticosteroids and systemic antihistamines. Severe disease may be treated with dapsone, which requires pretreatment screening for glucose-6-phosphate dehydrogenase deficiency and monitoring of complete blood count (CBC) and chemistry profile during treatment.

*Neonatal acne* occurs in 20% of healthy newborns. Onset is at approximately 2 weeks of age, and lesions generally resolve within 3 months. Small, inflamed papules occur on the nasal bridge and cheeks. Reports have implicated the yeast *Malassezia furfur* in the pathogenesis of neonatal acneiform eruptions. Given its benign and transient nature, reassuring the parents is generally adequate. If treatment is necessary, then benzoyl peroxide preparations or topical ketoconazole are effective.

*Incontinentia pigmenti* is an X-linked dominant genodermatosis caused by mutations in the *NEMO* gene. More than 700 cases have been reported; 97% of those affected are girls. The disease has 4 phases: vesicular (Figure 95-10), verrucous, hyperpigmentation (Figure 95-11), and hypopigmentation. In the vesicular phase, lesions are present at birth in 50% of those affected and in 90% of cases by age 2 weeks. Erythematous macules, papules, vesicles, and bullae follow the lines of Blaschko on the extremities, trunk, and scalp. The verrucous phase typically occurs between 2 and 6 weeks of age. Streaks of hyperkeratotic papules and pustules develop in the aforementioned areas. The third phase, hyperpigmentation, usually develops by 3 to 6 months of age. Hyperpigmented macules and patches are present along Blaschko lines. The final phase, hypopigmentation, exhibits during the second to

**Figure 95-10** Incontinentia pigmenti—vesicular phase.

third decades of life. Previously hyperpigmented areas develop hypopigmentation with or without follicular atrophy. Additional findings include scarring alopecia, abnormal teeth (anodontia; peg or conical teeth), eye abnormalities (strabismus, cataracts, optic atrophy, retinal vascular changes), dystrophic nail changes, and seizures. These patients typically have a normal life span. After the diagnosis has been made, a detailed family history and complete skin examination of the mother and of the child's sisters should be performed. Patients should have periodic complete physical examinations, ophthalmologic and neurologic examinations at diagnosis, and a dental examination by 1 year.

## INFECTIOUS LESIONS OF THE NEONATE

Skin infections of the neonate can be uncomplicated and benign or complex and life threatening. Most cutaneous infections are part of a distinct clinical spectrum. Generally, additional clinical clues assist in making a definitive diagnosis. Following are some commonly encountered skin infections that occur either at birth or during the first few weeks of life.

Sepsis is a potentially life-threatening diagnosis in the neonate. If a neonate is exhibiting signs of lethargy, irritability, fever, temperature instability, or poor feeding, then a sepsis workup is almost universally indicated. When present, cutaneous lesions of sepsis usually appear as polymorphic lesions, for example, erythematous macules, petechiae, or, less commonly, small nodules or vesicles. The workup includes cultures of blood, cerebrospinal fluid (CSF), and urine. Empirical antibiotics for the most common organisms should be initiated while awaiting culture results.

### Bacterial Infections

Neonates may exhibit cutaneous infections commonly encountered in school-aged children. Impetigo can be

**Figure 95-11** Incontinentia pigmenti—hyperpigmented phase.

seen during the neonatal period. Infection presents as well-demarcated areas of erythema that progress to vesicles and then pustules, which rapidly rupture or ulcerate, leaving a characteristic honey-colored crust. The most common pathogens are *Staphylococcus aureus* and *Streptococcus pyogenes*. Extremely limited local infections may be treated with topical antibiotics such as mupirocin; more diffuse involvement may require oral or intravenous antistaphylococcal penicillin or cephalosporin.

Bullous impetigo may occasionally be seen. It is caused by specific strains of toxin-producing *S aureus*. The lesion begins as an erythematous patch and progresses to bulla formation when exfoliative toxins are elaborated locally. Fluid obtained from these bulla may show gram-positive cocci in clusters. A diffuse eruption of superficial skin exfoliation is seen in staphylococcal scalded-skin syndrome. This form of staphylococcal infection is seen with the elaboration of exfoliative toxins secreted by phage-2 *S aureus* that is hematogenously disseminated. At the examination, the patient is febrile and seems ill. The patient's skin is diffusely tender and erythematous. Superficial bullae soon develop and quickly rupture. Application of pressure to the edge of intact skin will often result in separation of the epidermis from underlying skin layers (positive Nikolsky sign). Although Gram stain of this fluid will be sterile, neonates with suspected staphylococcal scalded-skin syndrome should have cultures obtained from their blood, urine, nasopharynx, or other suspected focus of infection. Patients with scalded-skin syndrome should be treated with parenteral antistaphylococcal antibiotics.

### Syphilis

With the advent of strict perinatal surveillance, the incidence of congenital syphilis has dramatically decreased. Occasionally, mothers without prenatal care can deliver a child with congenital syphilis. In early congenital syphilis, the neonate will exhibit symptoms similar to those of a patient with secondary syphilis. A generalized papulosquamous eruption can be found, including on the palms and soles. Additional features include rhinitis, hepatosplenomegaly, lymphadenopathy, fever, pseudoparalysis, and CSF abnormalities. Evaluation of patients with congenital syphilis includes serologic studies, CSF VDRL (Venereal Disease Research Laboratory) test, and CBC with platelet count. The treatment of choice is intravenous penicillin G.

### Viral Infections

Neonatal herpes simplex virus (HSV) infection can range from a mild, self-limited disease to one with potentially devastating neurologic consequences and even death. Approximately 70% to 85% of neonatal HSV infections are caused by the mother's primary HSV-2 infection being transmitted to the neonate; often, the mother has no evidence of genital herpes-like lesions at the time of delivery. HSV-1 is implicated in the remaining cases. Reactivation of the virus has very low rates of transmission to the infant. Neonatal HSV infection can exhibit in several forms. First, and potentially the most deadly, is central nervous system (CNS) disease. During a sepsis workup, HSV polymerase chain reaction (PCR) is usually performed on CSF obtained by lumbar puncture. PCR is now the method of

choice for documenting HSV CNS involvement. Because children generally tolerate intravenous acyclovir well, this drug should be provided after the lumbar puncture while awaiting the results of viral PCR. Second, neonatal HSV can produce classic skin lesions of grouped vesicles on an erythematous base seen anywhere on the body that may have been exposed to HSV during delivery. Tzanck preparations may show multinucleated cells if HSV is present. Viral culture of these lesions is the most definitive diagnostic method to establish the diagnosis of HSV. Finally, and least commonly seen, is disseminated infection, the symptoms of which often overlap those described previously. The physician must think of HSV infection as a clinical spectrum. Half of the cases of neonatal herpes in the United States are localized to the skin, eye, and mouth, which responds well to systemic acyclovir. However, in 20% to 25% of cases, dissemination to visceral organs occurs.<sup>72</sup> Lumbar puncture should be performed in any patient suspected of having neonatal HSV because of the possibility of CNS involvement. Intravenous acyclovir therapy should be initiated empirically while awaiting culture results.

Maternal infection with varicella-zoster virus during the first 20 weeks of gestation can result in congenital varicella syndrome. Affected infants can exhibit ophthalmologic complications, neurologic defects, limb hypoplasia, and genitourinary and gastrointestinal defects. Characteristic cutaneous findings are vesicles or scarring in a dermatomal distribution. Maternal varicella with onset during the last few weeks of pregnancy or during the early postpartum period can result in neonatal varicella. Affected infants have an eruption consisting of disseminated papules, vesicles (*dewdrop on a rose petal*), and erosions. Diagnosis can be made by Tzanck preparation, viral culture, or direct immunofluorescence assay. Infants are more likely to have severe disseminated disease with systemic complications if maternal onset of varicella is within 5 days of delivery to 2 days after or if the newborn exhibits the disease between 5 and 10 days of life. Neonatal varicella is treated with intravenous acyclovir.

Congenital rubella syndrome (CRS) occurs in infants of mothers exposed to rubella during the first portion (generally the first 16 weeks) of pregnancy. Increased risk for CRS is associated with earlier gestational exposure. The incidence of CRS has greatly declined as a result of widespread rubella vaccination; however, occasional outbreaks continue to be reported in populations with low vaccination rates. CRS is characterized by the triad of congenital cataracts, deafness, and cardiac defects (most commonly patent ductus arteriosus). Additional features include intrauterine growth restriction, various CNS manifestations, jaundice, hepatosplenomegaly, thrombocytopenia, and radiolucent metaphyseal bone lesions. The characteristic cutaneous finding is a diffuse eruption of blue-red papules and nodules (called *blueberry muffin lesions*). These lesions generally appear at birth or in the first 24 hours of life. Blueberry muffin lesions are not unique to CRS and can be seen in several additional congenital infections (toxoplasmosis, cytomegalovirus, parvovirus B19), erythroblastic fetalis, and neoplastic disorders (congenital leukemia, histiocytosis). Evaluation to determine the etiology

of blueberry muffin lesions should include a CBC, TORCH serologies, viral cultures, and Coombs test. A skin biopsy may also aid in the diagnosis. Additional nonspecific cutaneous features of CRS include nonspecific generalized maculopapular eruption, hyperpigmentation, and recurrent urticaria. The diagnosis of CRS should be suspected in infants with the appropriate constellation of findings. Confirmation is made by isolation of rubella virus from sputum, urine, CSF, or tissue, or by findings of increased titers of immunoglobulin M antibodies to rubella. Treatment is supportive. A high percentage of infants with CRS will experience significant neurologic and auditory complications. Prevention is through immunization with a live rubella virus vaccine.

### Yeast

Congenital *Candida* infection can be present at birth, or it can manifest within the first 6 days of life. Affected neonates typically have widespread eruption of macules, papules, and pustules with relative sparing of the diaper area. Thrush is uncommon in congenital candidiasis. Pustules of the palms and soles are a helpful diagnostic sign. Changes in the fingernails, including yellow discoloration and paronychia, are occasionally present. Diagnosis is made by potassium-hydroxide test or culture. The course tends to be benign in healthy neonates, but it may be complicated by systemic involvement in preterm neonates. Treatment for skin-limited disease in otherwise healthy neonates is with topical antifungal agents.

Neonatal candidiasis is most commonly caused by *Candida albicans* and is observed during the first and second week of life. Infection should be suspected in patients with white hypertrophic plaques within the oral cavity. Another common presentation is a localized perianal eruption consisting of erythematous macules and papules that become confluent. This eruption is often beefy red in color and characterized by the presence of satellite lesions (papules, pustules, or vesicles). The diagnosis can be made by potassium-hydroxide test and observing the characteristic pseudohyphae. Treatment of localized disease is with topical antifungal preparations.

Systemic candidiasis is typically seen in low-birth-weight infants between the second and sixth weeks of life. Features include temperature instability, lethargy, hypotension, and hyperglycemia. Cutaneous involvement may or may not occur. Diagnosis is confirmed by cultures of blood, urine, and CSF. High morbidity and mortality rates are seen in patients with this condition. Treatment is with amphotericin B.

### Chapter 96

## COMMON CONGENITAL ANOMALIES

Orna Rosen, MD; Robert W. Marion, MD;  
Joy Samanich, MD

The diagnosis of an anatomic abnormality in an infant at or around the time of delivery can be devastating for a family. From the time that a concern is raised, the parents, who have been anticipating the birth of a normal, healthy newborn, must contend with a series of uncertainties. They must comprehend the meaning of their child's diagnosis and adjust to the reality that their infant or their prospects for parenthood may be different from what they expected. Individual families handle this crisis in differing ways. The infant's primary care physician may need to assume different roles to assist and support the family.

Once a diagnosis has been made, identifying a cause for the malformation is essential for 3 reasons: to guide the workup in an attempt to identify associated hidden anomalies, provide anticipatory guidance for the family to aid in the decision-making process, and permit appropriate genetic counseling regarding the risk of a similar anomaly occurring in future pregnancies. In nearly 50% of cases, no clear cause will be found for the anomaly. In the other half, the anomaly is caused by either genetic disorders, consisting of both single gene mutations and chromosomal anomalies (Table 96-1), accounting for approximately 15% of cases; environmental exposures to teratogens, such as drugs and infectious agents, accounting for approximately 8%; or multifactorially inherited conditions, anomalies caused by an interplay between genetic and environmental factors, accounting for approximately 25% of anomalies.

Congenital anomalies, defined as abnormalities in form or function, occur in 2% to 4% of all infants born in the United States and are the leading cause of neonatal mortality and long-term chronic illness.

### DEFINITIONS

Birth anomalies can be classified as malformations, deformations, or disruptions. *Malformations* are localized

**Table 96-1** Common Genetic Disorders

DISORDER	MANIFESTATION	FREQUENCY PER 10,000 BIRTHS
<b>CHROMOSOMAL</b>		
Trisomy 21	Congenital heart disease, Brushfield spots, short hands, clinodactyly, simian crease, hypotonia, dysmorphic facies	16
Trisomy 18	Congenital heart disease, small for gestational age, clenched fist, rocker-bottom foot, dysmorphic facies	3
Trisomy 13	Congenital heart disease, small for gestational age, polydactyly, holoprosencephaly, dysmorphic facies	2
XO (Turner syndrome)	Congenital peripheral edema, webbed neck, short stature, primary amenorrhea	3
XXY (Klinefelter syndrome)	Behavior problems, small testes, infertility, clinodactyly	5
<b>AUTOSOMAL RECESSIVE</b>		
Sickle cell disease	Anemia, infection	20 (black)
$\beta$ -Thalassemia	Anemia	20 (Mediterranean)
Cystic fibrosis	Failure to thrive, malabsorption, cough, recurrent pneumonia	5 (white)
<b>AUTOSOMAL DOMINANT</b>		
Familial hypercholesterolemia	Family history of early coronary artery disease	20
Neurofibromatosis	Café-au-lait spots	3
<b>X-LINKED RECESSIVE</b>		
Fragile X	Mental retardation, large testes, dysmorphic facies	5
Duchenne muscular dystrophy	Muscle weakness, pseudohypertrophy of calf	1

errors in the morphogenesis of an organ that result in abnormal form or function from damage that has occurred to the primordial tissue during the first trimester of pregnancy. Malformations can be further classified as *minor* or *major*. Minor malformations, which occur in 1 of 10 newborns, are not associated with severe malfunction. They usually represent a cosmetic rather than a functional concern. In contrast, major malformations are far less common and cause severe functional consequences.

An *association* occurs when 2 or more malformations occur together more often than would be expected by chance. The underlying genetic cause of an association may not be known. VACTERL is an example of an association in which vertebral anomalies, anal atresia, cardiac anomalies, tracheoesophageal fistula, and renal and limb anomalies are combined.

A congenital structural abnormality or variation that occurs as a result of external physical forces will lead to a *deformation*. Oligohydramnios, uterine fibroids, and a multifetal pregnancy may each contribute to uterine compression that can result in clubfoot. A *disruption* is a congenital abnormality that occurs because of a destructive event or process that leads to incomplete or abnormal fetal development. Disruption of blood flow to a portion of the brain may result in porencephaly, whereas rupture of the amniotic sac produces tissue strands that entangle limbs, digits, or other fetal parts, leading to amputation of the affected fetal part and amniotic band syndrome. Malformations can occur alone or with other malformations (see Chapter 148, Facial Dysmorphism). They can be part of a *malformation sequence*, such as the Pierre Robin malformation sequence, or occur as part of a multiple malformation syndrome, in which all the anomalies

can be traced to a single identifiable cause (eg, an extra copy of chromosome 18 in trisomy 18, a mutation in a single copy of the *FBN1* in Marfan syndrome, exposure to alcohol in fetal alcohol syndrome).

## APPROACH TO THE NEONATE WITH CONGENITAL ANOMALIES

Identifying a congenital malformation in a newborn should begin a well-defined process of evaluation and information gathering. The physician should review the pregnancy and family history with the neonate's parents, perform a thorough physical examination, and order tests that will provide the information necessary to arrive at the decisions vital to the child's future.

Appropriate care, including resuscitation, should be initiated in the delivery room after the birth of a baby with congenital anomalies. The decision to withdraw treatment should be deferred until a full diagnostic evaluation has been completed and a diagnosis has been made, unless resuscitative efforts prove unsuccessful. Under certain circumstances an advanced care plan may be developed based on a confirmed prenatal diagnosis of a condition not compatible with survival and a family's decision made in consultation with their obstetric and pediatric care physician for their newborn to receive only comfort care. The parents must be involved from the beginning and have a major role in the decision-making process.

## Care of the Newborn With a Condition Not Compatible With Life

When a newborn is found to have an anomaly or syndrome that, in the judgment of the physicians, is

incompatible with life, some parents may have a difficult time accepting these facts and may resist the medical staff's counsel to withdraw life support or to consent to a *do not resuscitate* order. Parents may have difficulty agreeing to these types of recommendations for many reasons: some parents will be in denial about the child's condition, a normal part of the grieving process; others may object to withdrawal of care because of religious beliefs or personal values; still others may believe that, if given enough time, a miracle might occur or a new treatment might be developed that will save the infant's life. In such cases, to prevent the relationship between staff and family from becoming contentious, the medical staff must be as supportive of the family as possible. The caregiving team should maintain patience, empathy, and respect for the parents and for their values and preferences.

In all instances, particularly when disagreement exists between the medical team's management plan and the parents' wishes, lines of communication must be kept open. Daily meetings among the parents, their representatives (including members of the clergy), and the medical staff should be arranged; during these meetings, information about the child's condition should be discussed in detail and care options presented. The neonatal intensive care unit's social worker or hospital liaison psychologist should attend these meetings as a mediator or ombudsman. Parents may feel more comfortable discussing their feelings with a social worker or nurse than with the physician.

Under some circumstances, if no consensus can be reached, the team may have to engage the hospital's bioethics consultation team for mediation purposes or to provide an outside assessment of the information regarding the newborn's prognosis and appropriate treatment options, including the termination of therapy. Given adequate time, however, when the situation is handled with empathy, caring, and respect, the majority of disagreements between parents and physicians can be resolved without the intervention of a bioethics consultation committee or the involvement of the courts. In many instances, time, information, and support are the important elements that allow parents to come to terms with their child's diagnosis and the lack of corrective or palliative treatments, and to weigh the option of continuing care without the benefit of improvement versus discontinuing treatment except for comfort care and allowing their infant to die. If the child's death is not imminent, the parents may choose to take their newborn home to die or consider transfer to a chronic care hospital capable of providing hospice care. Engaging a family in a community- or hospital-based perinatal hospice program is another option. Although perinatal hospice is relatively new in the field of hospice care, the increasing frequency of prenatal diagnosis has created a need for this support for the family of the dying infant. (See Chapter 117, Support for Families Whose Infant Is Sick or Dying.)

### Role of the Medical Geneticist and Genetic Counseling

The genetic team plays an important role in the diagnosis and management of a newborn with congenital anomalies. By assisting in establishing the diagnosis

and providing counseling to the family, the geneticist and genetic counselor provide an important component of care. During the process of genetic counseling the genetic team supports the family, helping the parents and other family members cope with the issues that confront them. The team members serve as advocates for the patient, helping the parents process medical information and treatment options and assisting as needed with decision making. The genetic team becomes an ongoing source of assistance to the child and family by providing information in written and oral forms, making referrals to family support groups, and offering assistance with care coordination, financial aid, and social service needs.

## DIAGNOSIS

To reach a conclusive diagnosis in a newborn with congenital anomalies, 3 major aspects should be pursued: the medical history, the physical examination, and the appropriate laboratory tests.

### Medical History

A comprehensive history is an essential part of the evaluation of the baby with congenital malformations. Three elements that should be included in the history are the pregnancy history and prenatal course, the family history, and the delivery process.

Questions about the pregnancy should assess several areas (Box 96-1). First, how was the infant conceived? Evidence is growing that conditions caused by defects in gene imprinting, such as Beckwith-Wiedemann syndrome, occur more often in newborns conceived via in vitro fertilization.

Information about the nature of fetal movements can provide clues to the functioning of the newborn's central nervous system. Decreased fetal movements or delayed quickening suggests a neuromuscular disease, whereas a mother's report that her fetus had recurrent hiccups during the second or third trimester suggests possible intrauterine seizure activity. Oligohydramnios is suggestive of anomalies of the urinary tract, such as renal agenesis and obstructive uropathy, whereas polyhydramnios may point to an obstruction in the gastrointestinal tract, such as duodenal atresia or a disorder of the central nervous system that prevents normal fetal swallowing. The possibility of fetal exposure to a teratogenic substance should also be reviewed. Intrauterine exposure to alcohol raises concern about fetal alcohol syndrome, whereas exposure to drugs such as sodium valproate, carbimazole, vitamin A analogues, warfarin, and fluconazole is associated with specific malformation syndromes. Similarly, maternal infection with toxoplasmosis, rubella, cytomegalovirus, or varicella is responsible for well-defined patterns of malformations. Finally, chronic illnesses in the mother, such as poorly controlled diabetes mellitus and untreated phenylketonuria, can cause multisystem abnormalities in the fetus.

Results of prenatal testing can be helpful in determining the cause of a newborn's malformations. Prenatal karyotypes should be confirmed with a postnatal blood test from the baby. Antenatal alpha-fetoprotein levels that are too high or too low can direct the physician toward a specific diagnosis. An alpha-fetoprotein

**BOX 96-1 Areas to Cover When Taking a History****ISSUES ABOUT THE PREGNANCY**

1. Conception: Natural or assisted? If assisted, then what method was used to achieve this pregnancy? Were fertility issues raised related to maternal factors, paternal factors, or both?
2. Fetal movements: When did quickening occur? Were movements similar to, greater than, or less than those felt during previous pregnancies?
3. Amniotic fluid: Amount (polyhydramnios vs. oligohydramnios)—color, fluid leakage
4. Exposure: To teratogenic agents or maternal illnesses (diabetes, infection), maternal drugs or chemical use (street and prescription drugs), and environmental exposure (work or community exposures, radiation, hyperthermia)
5. Prenatal testing: Biochemical screening: Pregnancy-associated plasma protein-A, *Quadruple Screen* (Alpha-feto-protein, beta subunits of human chorionic gonadotropin, estriol, and inhibin-A). Use of maternal plasma-cell free DNA (cfDNA testing) in high-risk pregnancies to detect fetal autosomal aneuploidy has been recently reported.<sup>a</sup> Ultrasound screening for nuchal lucency, fetal growth, anatomy, blood flow in umbilical vessels, placental position, etc. Additional prenatal testing such as amniocentesis and chorionic villus sampling is available

6. Other: Parity, maternal weight gain, evidence of maternal uterine pathology (bicornuate uterus, fibroids, etc.), bleeding
7. Fetal growth: Appropriateness of growth, discrepancy in growth parameters—symmetric or asymmetric growth restriction, macrosomia or appropriate growth for gestational age

**ISSUES ABOUT THE FAMILY**

1. Complete pedigree
2. Presence of similar or dissimilar anomalies in first- and second-degree relatives
3. History of pregnancy losses: Spontaneous abortions, stillbirths, and neonatal demise in first- and second-degree relatives
4. Consanguinity in the parents

**ISSUES ABOUT THE DELIVERY**

1. Length of gestation
2. Type of delivery: If by cesarean section, then what was the indication?
3. Fetal presentation: Vertex, breech, or transverse lie?
4. Presence of placental or umbilical cord abnormality

<sup>a</sup>Bianchi DW, Parker RL, Wentworth J, et al. DNA sequencing versus standard prenatal aneuploidy screening. *N Engl J Med*. 2014;370:799–808  
 From: Marion RW, Fleischman AR. The assessment and management of neonate with congenital anomalies. In: Evans M, ed. *Reproductive Risks and Prenatal Diagnosis*. Norwalk, CT: Appleton and Lange; 1991. Reprinted by permission of The McGraw-Hill Companies, Inc.

level that is high raises a concern about a neural tube defect, abdominal wall defects, poor placental function or nephrosis in the fetus. A level that is too low could be caused by fetal death, increased maternal weight, overestimated gestational age, gestational trophoblastic disease, or trisomies. Ultrasound scans revealing shortening of long bones suggest a possible skeletal dysplasia. The presence of polyhydramnios and an ultrasound scan that shows a *double bubble* in the bowel suggest the diagnosis of duodenal atresia.

In gathering information about the family history, a pedigree consisting of at least 3 generations should be constructed (see Box 96-1 for questions to ask in taking the history). Detailed information about any malformations in family members should be obtained; any health problems, instances of intellectual disability, or known conditions should be noted. A history of still-born infants and spontaneous abortions suggests the presence of a balanced translocation in one of the parents, and should cause the physician to suspect that the newborn may have an unbalanced chromosome rearrangement. The presence of similar features in siblings may suggest that the disorder is genetic or a consequence of a teratogen. The physician should consider an inherited autosomal-recessive condition if parental consanguinity exists. Ethnic background, as well as country and city of origin, may suggest a specific genetic disorder that is more common in the

specific population or gene pool. Medical records of parents, siblings, or other family members should be reviewed to corroborate any significant positive findings elicited through the history.

Finally, information about the perinatal period should be obtained. How long was the gestation? Did the mother consume any medications, vitamins, or herbal or over-the-counter products before and during her pregnancy? Did the mother smoke, drink, or use any illicit drugs? Was the mother exposed to any environmental toxins (chemicals, vapors, or fumes, heavy metals or mercury, radiation)? Did the mother have any illnesses or chronic medical conditions? Did the mother have fever? Did any prenatal tests indicate a possible problem? How was the infant delivered? If delivery was via cesarean section, then what was the reason? What complications occurred during the delivery? What were the Apgar scores? Was resuscitation of the newborn needed? Was the placenta normal? Birth weight is particularly important, given that infants with chromosome anomalies, such as trisomy 18, and teratogenic syndromes, such as fetal alcohol syndrome, are typically small for gestational age, whereas babies with multifactorial disorders, such as cleft palate or meningomyelocele, or single gene mutations, such as Marfan syndrome, usually have normal birth weight, and infants born to diabetic mothers, as well as those with rare overgrowth syndromes, such

as Beckwith-Wiedemann syndrome, are typically large for gestational age.

### Physical Examination

A detailed, systematic physical examination should be performed. The newborn's weight, height, and head circumference should be recorded and plotted on an appropriate growth curve. Measurements that are not part of the standard newborn physical examination should be included in the evaluation of the neonate with congenital anomalies. These measurements include interpupillary distance and interpupillary distance, length of philtrum, and ear size and position. Each part of the limbs should be measured. In the newborn period the upper body/lower body ratio is approximately 1.7:1. If this ratio is too high, then the extremities are short; if the ratio is too small, then either the limbs are long or the trunk is too short. During the physical examination, when the upper extremities are in extension and adducted against the body, the tips of the fingers should reach approximately mid-thigh. If the fingertips only reach the hip joint, then the limbs are too short. Comparison of limb length and the ratio of upper body to lower body segment with standard measurements for a newborn may lead to a diagnosis of skeletal dysplasia.

Features that are important in diagnosing the newborn with major congenital malformations are reviewed in the following sections.

### Skull

Evaluation of the skull in the immediate newborn period may be difficult because the journey through the birth canal may produce a molded or misshapen skull. In most cases the skull will revert to its more normal shape within 48 hours.

Craniosynostosis is the premature closure of 1 or more sutures of the skull. The newborn with craniosynostosis will have an unusual skull shape that does not resolve during the first few days of life. The shape of the skull depends on the suture or sutures that have fused: scaphocephaly or dolicocephaly, a long, *boat-shaped* head, results from closure of the sagittal suture; brachycephaly, a short, broad skull, results from coronal suture closure; plagiocephaly, a rhomboid-shaped skull, results from premature closure of either a single lambdoidal or coronal suture (see Chapter 316, Positional Deformational Plagiocephaly); Kleeblattschädel or cloverleaf skull occurs when multiple sutures fuse early during gestation. Craniosynostosis can be an isolated finding in an otherwise normal infant, arise because of an underlying metabolic or endocrinologic disorder, such as hyperthyroidism, or be part of a multiple malformation syndrome, such as Crouzon, Apert, or Pfeiffer syndromes.

An unusual skull shape is not always associated with premature closure of sutures. Brachycephaly is a feature of Down syndrome; scaphocephaly or dolicocephaly can be seen in neonatal Marfan syndrome. Other malformations of the skull or scalp can provide important clues to the diagnosis. For instance, newborns with trisomy 13 often have aplasia cutis congenita, a punched-out-appearing scalp defect

usually seen in the occipital region. The presence of such a lesion in a child with polydactyly and other malformations is virtually pathognomonic for this lethal chromosomal disorder.

### Face

A detailed discussion of facial dysmorphism is found in Chapter 148, Facial Dysmorphism. The approach to evaluating infants with minor (common) facial malformations is reviewed below.

The eyes should be measured to obtain the palpebral fissure size (measured from inner to outer canthus) and interpupillary and inner canthal distances and to determine if the infant has hypotelorism or hypertelorism that is associated with many syndromes. Syndromes with hypotelorism as a feature include trisomy 13 and 21, holoprosencephaly, Meckel-Gruber syndrome, and Williams syndrome, among others. Corneal opacity suggests the possibility of many genetic disorders or a metabolic disorder like mucopolysaccharidosis syndrome. Upper slanting eyes, epicanthal folds, a flat nasal bridge, and short nose with anteverted nares that occur in combination are indicative of midfacial hypoplasia and are seen in infants with Down syndrome and fetal alcohol syndrome, whereas downward slanting of eyes is present in the infant with Treacher Collins.

The ears should be thoroughly examined. The length and shape of each ear should be measured and assessed for low set ears and preauricular skin tags or pits. Ear anomalies are commonly associated with genetic syndromes. Preauricular tags and pits are common findings on the newborn examination. Ear pits and tags can be inherited in an autosomal-dominant pattern. The physician should therefore check other family members for ear pits and tags, as well as to screen the newborn for hearing loss. Defects in middle ear and inner ear can accompany external ear abnormalities. The neck should be examined for branchial pits. If present, then it may be part of the branchio-oto-renal syndrome, and a renal ultrasound should be performed. Renal sonography should be considered when at least 3 minor anomalies exist that include preauricular pits or tags. The diagnostic yield of renal sonography is low for babies who have isolated pits or tags.

The mouth, including philtrum length, should be measured. A large mouth (macrostomia) or small mouth (microstomia) may be seen in various genetic syndromes. Some newborns will exhibit an asymmetric cry caused by the absence of the depressor anguli oris muscle. The cause of this defect is considered to be multifactorial. Research has shown that babies with asymmetric cry have a higher incidence of congenital heart disease; the most common defects include ventriculoseptal defect, atrial septal defect, patent ductus arteriosus, and tetralogy of Fallot. An asymmetric cry is associated with anomalies in other systems, including the central nervous, gastrointestinal, urinary, and skeletal systems. Association with velocardiofacial syndrome (22q11 deletion syndrome) has been reported. Some children have developmental disabilities and failure to thrive. Babies who are born with asymmetric cry should be checked thoroughly for cardiac and other anomalies. Prominent

lips suggest Williams syndrome, whereas a thin upper lip is seen in fetal alcohol and Cornelia de Lange syndromes.

Cleft lip, with or without a cleft palate, occurs in approximately 1 in 750 live births among white infants and is more common in male infants than in female infants. The incidence is highest among Asian infants and lowest in black infants. Cleft lip is usually located laterally at the philtrum ridges. A cleft located in the midline should alert the physician to suspect holoprosencephaly and to assess for other midline central nervous system defects. Cleft lip and palate can occur sporadically as part of a malformation syndrome or as the consequence of maternal drug exposure or a genetic trait. Isolated cleft palate occurs less frequently, at a rate of 1 in 2,500 live births. Cleft defects are associated with other malformations in 25% to 50% of affected infants. An isolated cleft lip does not typically cause functional problems. The primary concern is cosmetic, and this defect may cause a great deal of anxiety for the family. Parents need support and reassurance about the frequent success of cosmetic repair. Feeding problems in the neonatal period often present a significant challenge. Infants who have a cleft palate often cannot adequately generate the negative pressure during sucking to feed efficiently using a standard infant nipple. Many techniques may be tried; however, use of a soft nipple with larger holes and squeezable bottle is often sufficient to solve the problem. Infants with cleft palates can successfully breast-feed with proper support, education, and assistance from a lactation consultant. The mandible is usually retruded in the neonatal period. If the mandible is underdeveloped but the infant has a normal-size tongue, then space is insufficient to contain the tongue properly, leading to pressure on the palate. This process may produce a U-shaped cleft, similar to that seen in infants with Pierre Robin sequence.

Cleft lip repairs are typically performed when the infant is 2 to 3 months of age, after the baby has gained weight and adjusted to extrauterine life. Correction of cleft palate occurs between 9 and 12 months of age.

### **Chest**

The chest circumference and the internipple distance should be measured and plotted on an appropriate growth curve. The nipples may be widely spaced in Turner and Noonan syndromes. A constricted chest with a smaller than normal circumference often occurs in skeletal dysplasias involving the spine, such as Jeune asphyxiating thoracic dystrophy and Ellis van Creveld syndrome; these disorders are often associated with lung hypoplasia, a feature that may impair the infant's ability to survive. Under normal circumstances the head circumference is larger than the chest circumference by 1 to 4 cm; if these proportions are different, then a cause should be sought. Shortening of the sternum is a common feature in trisomy 18, whereas short trunk is seen in skeletal dysplasias such as osteogenesis imperfecta.

### **Spine**

Open neural tube defects are common congenital anomalies, although their frequency has decreased

significantly since the advent of folic acid supplementation of grains and grain products. Since 1998 the availability of periconceptual folic acid has decreased the occurrence of open neural tube defects by approximately 70%. Open neural tube defects include meningocele (the presence of both neural elements and cerebrospinal fluid in a sac protruding from the midline of the back), meningocele (the presence of just cerebrospinal fluid with no neural elements), anencephaly, and encephalocele (essentially, meningocele of the skull). Spina bifida occulta, a condition in which the vertebral arches are not complete and the spinal cord is intact, is a common minor malformation that is of little clinical consequence. Not etiologically related to open neural tube defects, spina bifida occulta may, in rare cases, be associated with tethering of the spinal cord. Similarly, skin lesions or minor abnormalities such as tufts of hair in the lumbosacral region can be an occult marker of underlying cord disease, such as lipomas, or tethers.

When the primary care physician examines a neonate and observes 1 or more of the skin manifestations mentioned previously, the question arises as to whether an ultrasound of the spine is required to rule out a spinal anomaly. Kriss and Desai described a 3.5% incidence of simple sacral dimples (<5 mm, midline position, not farther than 2.5 cm from anus, and no other skin lesions) among 1,449 term infants; none of these infants had spinal abnormalities. They did observe that the infants with other lower back skin lesions (hemangiomas, tail-like skin appendages, raised skin lesions, hairy patches, and cutis aplasia) and a more complex sacral dimple (>5 mm and farther than 2.5 cm from the anus) are at high risk for spinal dysraphism, more so if the baby has more than 1 finding. (See Chapter 332, Spina Bifida.)

### **Trunk and Limbs**

The limbs are involved in many congenital malformation syndromes. In the initial examination the newborn should be examined for symmetry, mobility, and length. Are the head and the trunk appropriate in size for the body? If not, then are the limbs too short (suggesting a skeletal dysplasia such as achondroplasia), or is the trunk too short for the limbs (suggesting a skeletal dysplasia of the spine, such as Jeune syndrome or spondyloepiphyseal dysplasia congenita)?

Asymmetry of the limbs can be caused either by atrophy, often the result of an intrauterine vascular disturbance such as Poland sequence, or by hypertrophy, as can be seen in Beckwith-Wiedemann syndrome or hemihypertrophy, each of which may be associated with Wilms tumor and other malignancies.

Decreased mobility of joints and congenital contractures, often termed arthrogryposis multiplex congenita, results from conditions that interfere with normal fetal movements. Congenital contractures can result from a primary neuromuscular disorder or occur secondary to fetal crowding in the uterus (caused by oligohydramnios, bicornuate uterus, other uterine malformations, or multiple fetuses).

Talipes equinovarus, more commonly known as clubfoot, is a deformity that includes hindfoot plantar flexion, midfoot cavus, and adduction and supination

of the forefoot. It is a common anomaly, occurring in 1 to 2 per 1,000 live births. The most common form is idiopathic clubfoot, which is most likely the result of a combination of environmental and genetic factors. A positional clubfoot may result from intrauterine crowding with restriction of foot motion, and lacks the stiffness of an idiopathic clubfoot. Similarly, a paralytic clubfoot results from intrinsic lack of intrauterine motion. The most rigid and deformed clubfeet are usually teratogenic or syndromic; as the name suggests, these foot deformities are associated with other congenital anomalies such as arthrogryposis and skeletal dysplasias. Talipes is a common feature of a number of multiple malformation syndromes, including trisomy 13 and 18. Tredwell reported association of talipes equinovarus with early amniocentesis. Casting is available as a nonoperative treatment. The cast is changed every 1 to 2 weeks with the expectation of repair within 3 months. The patient continues to wear a cast for 3 to 6 months, followed by corrective shoes. If casting fails, then surgical repair is undertaken. Recently, the Ponseti casting technique involving tenotomy of the Achilles tendon has become well accepted. The casting is followed by bracing for 2 to 4 years.

Isolated puffiness of the hands and feet, particularly on the dorsal side, suggests lymphedema; the physician should suspect Turner syndrome or Noonan syndrome.

Polydactyly, the presence of extra fingers or toes, a common finding, is often inherited in an autosomal-dominant fashion. Polydactyly is usually an isolated finding in an otherwise healthy newborn, occurring in approximately 1 in 700 live births. However, the finding of extra digits can also be part of a more complex multiple malformation syndrome. Classification of polydactyly is based on the position of the extra digit on the hand or foot. The extra digit can be on the radial (preaxial) side of the hand or, more commonly, on the ulnar aspect (postaxial); the digit can be represented by boneless soft tissue attached by a rudimentary pedicle (postminimus) or can be a normally functioning digit. Postaxial polydactyly occurs more often than preaxial polydactyly, particularly among black individuals. When preaxial polydactyly is present, a possible syndromic association should be sought, particularly if a triphalangeal thumb is present. Holt-Oram syndrome, short ribs–polydactyly syndromes, Carpenter syndrome, trisomy 21, VACTERL association, and Fanconi anemia are conditions that may be associated with preaxial polydactyly. Rarely, central polydactyly affecting the 3 central digits may occur. The least common type of polydactyly, it is often associated with another malformation or a syndrome.

Syndactyly, an abnormal connection between adjacent digits, can involve only soft tissues (simple) or include bones (complex). It may be either complete, along the entire length of the finger, or incomplete, sparing the distal part of the fingers. Any number of digits can be linked. Syndactyly is relatively common, affecting 2 to 3 of 10,000 live births. The anomaly can be sporadic, familial, or associated with other abnormalities. Familial syndactyly usually affects the second and third digits and is not associated with other

abnormalities; transmission is autosomal dominant, with variable expressivity and incomplete penetrance. Associated or complicated syndactyly can be syndromic or secondary to a constriction band (amniotic band) sequence. Syndromes described in association with complicated syndactyly include acrocephalosyndactylies and the Poland sequence.

Brachydactyly, or foreshortening of digits, can be isolated or part of a large number of syndromes, or elongated (usually referred to as arachnodactyly), a feature of Marfan syndrome. The position of digits can be abnormal. Clinodactyly, referring to an incurving of 1 or more digits (most often the fifth finger), is a common finding in healthy individuals but is associated with Down syndrome and Russell-Silver syndrome. Camptodactyly, a contracture of the proximal interphalangeal joint most commonly affecting the third and fourth digits, is caused by shortening of the tendons, can be an isolated finding, and is often inherited as an autosomal-dominant trait or part of a more complex condition such as Beals contractural arachnodactyly syndrome or trisomy 18.

### Genitalia

Immediately after birth, the first question asked by parents is whether their infant is a boy or girl. When the answer to this question is not clear, the parents will be understandably anxious and confused. Because of the delicate nature of this problem and the need to communicate with the family in a timely and accurate manner, the management of the infant with ambiguous genitalia is considered a true medical emergency. The evaluation and management of the infant with ambiguous genitalia require a coordinated approach to care that includes a neonatologist, an endocrinologist, a pediatric urologist, a geneticist, a social worker, and mental health professionals. Throughout the evaluation and treatment process, open and frequent communication with the infant's family is essential. In the past, if a baby had a micropenis or severe hypospadias, then the recommendation was for gender reassignment with genital surgery started as soon as possible. Today, controversy exists regarding gender reassignment. The current approach avoids any irreversible surgeries to the genitalia until the child's own gender identity is clear. (See Chapter 243, Disorders of Sex Development.)

Hypospadias is a common malformation of the male genitalia occurring in 1 in every 200 male infants. (For a complete discussion see Chapter 94, Physical Examination of the Newborn; and Chapter 272, Hypospadias, Epispadias, and Cryptorchidism.)

Testicular location is an important clue to whether hypospadias is an isolated defect or part of a more complex condition. Hypospadias is more likely to be an isolated defect in the individual in whom the testes are both descended. Isolated hypospadias, as with clefting of the lip and palate, is a multifactorial trait that shows clustering in families. As such, in these individuals, finding a positive family history is not unusual. The finding of cryptorchidism in an individual with hypospadias should trigger a more extensive workup than would be performed on the child with isolated hypospadias. Such individuals

may actually be virilized girls, caused by such underlying conditions as congenital adrenal hyperplasia resulting from 21-hydroxylase deficiency, partial androgen insensitivity, abnormalities of the sex chromosomes, or another endocrinologic or genetic syndrome. The physician should inquire about the use of progestin and other hormonal treatment in the first trimester; the child should be evaluated for the presence of ovaries and uterus, and renal and other somatic anomalies, and also tested immediately to rule out congenital adrenal hyperplasia. Finally, a karyotype and endocrinologic testing are necessary if intersex is suspected.

Clitoromegaly, enlargement of the clitoris, is not a common finding. In premature babies the labia majora are not yet fully developed, and the normal-size clitoris seems unusually prominent. As described by Oberfield, the paired diameter of the corpora cavernosa should be measured. When enlargement is caused by trauma (edema caused by the birth process), then the diameter will be less than 6 mm. When the enlargement is caused by excess of androgens, then the diameter of the paired corpora cavernosa is more than 6 mm. The infant must be evaluated for congenital adrenal hyperplasia, given that replacement therapy is lifesaving.

## DIAGNOSTIC PROCEDURES

### Chromosome Analysis

Recently, clinical genetic testing using microarray technology has made it possible to detect much smaller chromosomal deletions and duplications (copy number changes) than was possible by standard or high resolution chromosome analysis. Chromosomal microarray (CMA) involves extraction of DNA from peripheral blood and comparison of DNA copy number with a “normal” DNA sample. While similar to fluorescent in situ hybridization (FISH), this technique allows the detection of DNA copy number changes throughout the genome, rather than only at a specifically designated locus. A caveat to the use of microarray testing is that many copy number variants (CNVs) have been discovered, which are benign variants and not disease-causing. The interpretation of test results may require comparison with parental DNA or discussion with a molecular cytogeneticist, or may remain inconclusive. Additionally, CMA cannot detect balanced rearrangements, including translocations or inversion. CMA should be ordered for any child with 2 or more major anomalies, many minor anomalies, intellectual disability, or autism spectrum disorders.

Chromosome analysis is performed on any cells that have the ability to actively divide in culture. As such, although the test is usually performed on lymphocytes from peripheral blood, bone marrow cells or fibroblasts from skin biopsy can also be used. When lymphocytes are used, results should be available after 3 to 4 days; karyotype from fibroblasts takes much longer, on the order of 4 weeks or more. If chromosome analysis can be performed on bone marrow, the results will be ready in 1 day. This method is usually reserved for cases in which critical decisions regarding management need to be made. Chromosome analysis is used to

detect major numerical or structural chromosomal abnormalities, and should be performed in any newborn with ambiguous genitalia or features of a known chromosomal abnormality such as trisomy 21, or if a balanced chromosomal translocation is suspected.

If trisomy 21 or another condition caused by aneuploidy is suspected, then routine chromosome analysis should be ordered. If the child’s features do not fit one of these well-described conditions, then it is more appropriate to order high-resolution chromosome testing, which will provide a more detailed analysis of the chromosomes. Some diseases are caused by a large deletion of an entire gene that can be detected by FISH and other molecular cytogenetic methods.

### Single Gene Testing

Polymorphisms, the most common cause of changes in DNA base pairs, do not cause disease. When an alteration in a gene leads to an alteration in function with clinical symptoms and signs, it is called a *mutation*. Most genetic diseases are caused by single base pair deletions, duplications, or substitutions.

DNA analysis permits the identification of a growing number of conditions caused by single gene mutations. Updated information can be found at GeneTests ([www.genetests.org](http://www.genetests.org)), a Web site that provides information about the availability of testing for specific genetic conditions. New technology, referred to as next-generation sequencing, is being developed to analyze the sequence of multiple genes in a single test. This will aid in the diagnosis of disorders that can be caused by mutations in many different genes and in the discovery of genes responsible for currently unexplained genetic syndromes.

### Fluorescent in Situ Hybridization

FISH is a useful technique in babies born with congenital malformations that suggest one of a group of conditions known to cause small chromosome deletions or duplications. FISH should be ordered in infants in whom the following conditions are being considered: Velocardiofacial or DiGeorge syndrome (deletion 22q11.2), Williams syndrome (deletion 7q11.23), cri du chat (deletion 5p), and lissencephaly and Miller-Dieker syndrome (deletion 17p13.3).

### Methylation Testing

Addition of a methyl group to cysteine and adenine nucleotides can silence or down-regulate gene expression. There is a differential pattern of methylation based on whether the chromosome is of maternal or paternal origin. Through genetic analysis, this change can be exploited to determine the methylation pattern that exists on the genome. Diseases that are caused by methylation abnormalities such as Beckwith-Wiedemann, Prader-Willi, and Angelman syndromes can be diagnosed by determining the methylation pattern in the genome.

### Metabolic Tests

Metabolic tests are additional tools to confirm a diagnosis in a baby with congenital anomalies or a suspected syndrome. Increasing numbers of conditions exist in which a connection between the clinical diagnosis and

the biochemical abnormality has been established. For instance, hypocalcemia is seen in velocardiofacial (DiGeorge) syndrome, whereas hypercalcemia is not uncommon in Williams syndrome; hypoglycemia, caused by hyperinsulinism, is seen in Beckwith-Wiedemann syndrome, whereas low cholesterol and increased level of 7-dehydrocholesterol is a confirmatory test for Smith-Lemli-Opitz syndrome.

### Imaging

Imaging studies are indicated when a baby has more than 1 major anomaly or several minor abnormalities. The finding of internal abnormalities will help in establishing a diagnosis and optimizing treatment of the newborn. Ultrasound of the head and abdomen may detect major anatomic defects. The kidneys should be checked as well. A magnetic resonance imaging study for the brain is the preferred diagnostic tool rather than cranial sonography; however, if a newborn is unstable, then sonography may be the appropriate first screening tool. A skeletal survey is indicated when shortening of limbs or significant short stature at birth is present. Review of a chest radiograph for the presence of the thymus is helpful if 22q11 deletion is suspected; in many syndromes the number of ribs is abnormal. In suspected craniosynostosis a skull film or three-dimensional head computed tomography is helpful, whereas patellar or epiphyseal stippling can be seen in Zellweger syndrome. Periosteal cloaking of long bones is present in I-cell disease even if the baby is preterm. An echocardiogram should be obtained on any neonate with a heart murmur who has other malformations. Ophthalmologic evaluation is helpful as well. Corneal opacity is seen in mucopolysaccharidosis and trisomy 18, colobomata of the iris in CHARGE syndrome (coloboma, heart disease, atresia choanae, retardation of growth or development, genitourinary tract anomalies, and ear anomalies), trisomy 13, cataracts in Sotos syndrome, and Stickler syndrome, as well as other syndromes.

### Other Diagnostic Tools

The diagnosis of a malformation syndrome is sometimes apparent on the basis of the infant's clinical features. A diagnosis will sometimes be determined after additional testing. To address the difficulty in determining a diagnosis, dysmorphologists have developed scoring systems for various genetic syndromes. Scoring systems have been developed for trisomy 18, as well as trisomy 21, Williams, Cornelia de Lange, and Noonan syndromes. The limitation of a scoring system is the subjective judgment of the examiner. Another helpful tool is *Smith's Recognizable Patterns of Human Malformation*, which describes lists of anomalies that appear in different syndromes. Computer systems such as POSSUM (Pictures of Standard Syndromes and Undiagnosed Malformations), LDDb (London Dysmorphology Database), and SYN-DROC (Syndrome Congenital Malformation Database) have been developed; these programs can be helpful in identifying malformation syndromes.

### Special Concerns

Genetic testing should not occur before pretest counseling of the family. Counseling should include discussion that genetic test results may disclose

information about the extended family and even lead to revelation of family secrets about paternity or adoption. Both family members who are carriers of the disease and those who are healthy may experience a range of feelings, including anger and guilt. In October 2009, the federal Genetic Information Nondiscrimination Act (GINA) was signed into law, preventing citizens from being discriminated against by health insurers or employers because of their genetic test results. However, genetic test results can affect family members' ability to obtain life and disability insurance, or to adopt children. Special consideration should be given to genetic testing in children who are not capable of giving informed consent; for this reason, several national organizations, including the American Academy of Pediatrics, published recommendations under which children should be allowed to have genetic testing: "(1) When there are immediate medical benefits, such as institution of measures that can prevent the disease, delay its onset, or prevent secondary disabilities; and (2) when there is benefit to another family member and no harm to the minor." When parents request genetic testing and no benefits exist for the child, or if the genetic testing will be used solely for future reproductive decision making, then in most circumstances the test should be deferred. Genetic testing brings complex social, ethical, and emotional issues, particularly in adolescents. Before ordering any genetic tests the physician must understand the above complexities, consult with the appropriate specialists, and prepare the family for the possible consequences of the genetic testing results.

## TOOLS FOR PRACTICE

### Medical Decision Support

**Chapter 97****POSTNATAL ASSESSMENT  
OF COMMON PRENATAL  
SONOGRAPHIC FINDINGS**

Deborah E. Campbell, MD; Sheri L. Nemerofsky, MD;  
Abieyuwa Iyare, MD; Teri Jo Mauch, MD, PhD;  
Richard M. Schwend, MD

Approximately 10% of all neonates are born with a birth defect. Three percent will have a serious, potentially life-threatening anomaly, and an additional 7% to 8% of neonates are born with a minor malformation. Advances in prenatal screening, diagnosis, and intervention have contributed to an increased awareness at the time of birth of newborns in need of postnatal evaluation to confirm a prenatal diagnosis. For those newborns with a confirmed prenatal diagnosis, this information permits more rapid initiation of treatment and can help guide the evaluations necessary to optimize care. The patterns of malformations seen among newborns have changed over time because of prenatal diagnosis, availability of fetal interventions (including many experimental protocols), and families choosing termination of pregnancy in instances in which the fetus has multiple or complex malformations with an associated poor prognosis or a lethal chromosomal or genetic condition. The spectrum of antenatal sonographic findings is extensive and beyond the scope of this chapter, the focus of which is on the healthy-seeming newborn whose prenatal history is notable for a suspected antenatal abnormality. For further information, see Chapter 96, Common Congenital Anomalies; and Chapter 154, Foot and Leg Problems.

Prenatal diagnosis, though offering the potential for earlier intervention and correction of potentially serious abnormalities, also presents a significant psychological burden on expectant women and their families that may have long-lasting effects. Prospective parents are aware that prenatal ultrasound is a tool for early diagnosis of some abnormalities; however, often they are primarily interested in confirmation of pregnancy and a connection to their baby. The benefits of prenatal sonographic screening on neonatal outcomes remain largely unproven because the sensitivity and specificity of prenatal sonographic screening varies with the conditions screened for, the maternal habitus, and the time at which testing is performed. Routine prenatal screening is useful in the estimation of gestational age, detection of multiple gestations, and identification of fetal anomalies. Accurate pregnancy dating is important in preventing unindicated late preterm and early term deliveries (before 39 weeks' [39 $\frac{0}{7}$ –39 $\frac{6}{7}$  weeks] gestation) and in appropriate diagnosis of intrauterine growth restriction, and in reducing intervention for postterm pregnancy. Appropriate pregnancy dating is also important for more accurate detection of aneuploidy because the significance of the first trimester maternal serum screening test results (free- $\beta$  human chorionic gonadotrophin and

pregnancy-associated plasma protein-A) is based on the estimated gestational age. Generally, 1 to 2 prenatal ultrasounds are performed during every pregnancy. The first study is usually performed between 11 and 14 weeks' gestation in order to confirm an intrauterine pregnancy and to assess for evidence of nuchal translucency (sonographic appearance of a subcutaneous fluid collection behind the fetal neck). Fetal nuchal translucency thickness measurements combined with maternal serum screening markers can detect over 90% of fetuses with trisomy 21. Fetal anatomic scans are typically performed during the second and third trimesters of pregnancy. The sensitivity of sonography performed during the second trimester for detecting fetal anomalies ranges from 35% to 75%. When performed during the second trimester, prenatal sonography identifies approximately 92% of central nervous system (CNS), 80% of musculoskeletal, 60% of genitourinary, 50% of craniofacial, and 24% of cardiovascular malformations (38% if the child's underlying condition is associated with congenital heart defects), with many of these abnormal findings not being of clinical significance. (See Table 97-1.)

Some anomalies may not yet have developed, such as microcephaly. Detection rates are variable and dependent on gestational age at examination, type of malformation, sonographer experience, number of ultrasounds performed, quality of the equipment used, and population characteristics. Fetal magnetic resonance imaging and fetal karyotyping may be used to further delineate clinical findings and aid in the formulation of the initial clinical care plans for the fetus and neonate. Some infants with prenatally diagnosed conditions will be healthy when evaluated postnatally. Despite explanations from obstetric caregivers and sonographers that prenatal ultrasonography will not identify all anomalies, families often expect that any and all problems should have been detected if the mother had 1 or more prenatal sonographic studies or underwent an amniocentesis. This expectation can present a challenge to the pediatrician who must assist the parents as they come to terms with their newborn's diagnosis and try to understand the limits of technology.

Screening ultrasonography has not been shown to be more effective in improving perinatal outcomes

**Table 97-1****Likelihood of Malformation  
Detection on Prenatal  
Sonography**

ANOMALY	CHANCE OF DETECTION
Anencephaly	99%
Hydrocephalus	60%
Spina bifida	90%
Major cardiac anomalies	25%
Diaphragmatic hernia	60%
Omphalocele/gastroschisis	90%
Major renal anomalies	85%
Major limb anomalies	90%
Trisomy 21	40%

compared with selective use of ultrasonography based on clinical judgment. However, if fetuses with severe malformations whose pregnancies are terminated are excluded from statistical analyses, then an improvement in reported outcomes can be found. Controversy exists with regard to the benefits of prenatal diagnosis, given that decision making about the choice of delivery hospital, level of neonatal and subspecialty care, and initial scope of care provided are influenced by the available prenatal data. The infant with a serious malformation, such as a gastroschisis or congenital diaphragmatic hernia (CDH), can benefit from delivery at a tertiary care center, while knowledge that an infant has a ductus-dependent cardiac lesion can afford the pediatric primary care physician the opportunity to have prostaglandin therapy available for use during the infant's stabilization. In contrast, postnatal diagnosis of significant birth defects, such as pulmonary atresia, may not necessarily lead to greater mortality or morbidity in comparison with infants who are identified through prenatal screening. Understanding the complexities of screening is important in assisting parents as they assimilate information about health conditions for their baby, their awareness of the potential problem in the prenatal period, and subsequent evaluation of the infant to characterize more fully the infant's health care needs.

Surveillance programs in the United States report that orofacial clefts and Down syndrome are the most common major birth defects to occur among liveborn infants. The Metropolitan Atlanta Congenital Disorders Program is a Centers for Disease Control and Prevention (CDC)-supported initiative that tracks birth defects in that city. When all neonatal birth defects are considered, malformations involving the heart, genitourinary, and musculoskeletal systems, as well as the chromosomal anomaly trisomy 21, are among the more common abnormalities observed. The most frequently observed cardiovascular malformations are atrial septal defects, patent ductus arteriosus, and ventricular septal defects, in increasing order of prevalence. Rates of gastroschisis are also reported to be increasing, particularly among teen mothers. Regional variation has been reported in the incidence of these and other malformations; the reasons for the changing prevalence rates are not easily determined in many instances. It is important to recognize the variability in the clinical significance of the various findings detected by prenatal sonography, the potential psychological effect for families, which prenatal findings require postnatal assessment, and the scope of evaluation required.

## POSTNATAL EVALUATION IN OTHERWISE HEALTHY NEWBORNS

### Abnormalities in Amniotic Fluid Index

Amniotic fluid helps to protect the fetus in utero from impact, allows the fetus to move freely around the uterus, and promotes fetal lung development. Amniotic fluid is produced by the mother until about the fourth month of pregnancy when the fetal kidneys begin to produce urine. Amniotic fluid volume increases until about 32 weeks' gestation, and then proportionately decreases as the fetal size increases. The amniotic

fluid index is measured by the sum total of the deepest vertical pockets in each of the 4 quadrants into which the uterus is divided. Normal amniotic fluid index (AFI) is 5 to 24 cm. Infants who have abnormal amniotic fluid volumes require careful review of prenatal history and a thorough physical examination.

Oligohydramnios, defined as an AFI less than 5 cm, occurs in about 4% of pregnancies. A strong correlation has been reported between an AFI less than 5 cm and abnormal fetal heart rate, meconium passage during labor, and the need for cesarean delivery. Decreased production of amniotic fluid may be associated with renal anomalies. In the absence of malformations, borderline or low AFI is more likely to be complicated by fetal growth restriction and preterm birth. Decreased volume of amniotic fluid inhibits the activity and movement of the unborn infant. This is associated with a greater prevalence of congenital torticollis and developmental hip dysplasia compared to controls. Oligohydramnios may result from renal malformations; therefore, in instances where an underlying cause for the oligohydramnios has not been determined prenatally, a postnatal sonogram is recommended and consideration should be given to measurement of serum chemistries and perhaps additional imaging (voiding cystoureterography [VCUG], Mag3 renogram) based on the results of the initial evaluation. Postnatal hip ultrasounds and/or radiographs should be ordered for cases of prenatal diagnosis of oligohydramnios and breech positioning. Careful newborn and periodic physical examinations of the hips should be done for these children as well as hip ultrasound between 4 weeks and 4 months of age and/or radiograph after age 4 months.

Polyhydramnios, defined as an AFI greater than 24 cm, occurs in 1% to 3% of pregnancies. Polyhydramnios is a common finding in diabetic pregnancies, when the fetus is macrosomic, as well as in multiple gestation pregnancies. There is an increased risk for minor (4.2%) as well as major (20%) congenital malformations in pregnancies where polyhydramnios is present including GI (40%), CNS (26%), cardiovascular (22%), or genitourinary system anomalies (13%). Gastrointestinal malformations include GI tract obstruction, such as duodenal atresia and tracheoesophageal fistula. Approximately 50% of affected pregnant women had no associated risk factors. Among monoamniotic-monochorionic twin gestations complicated by twin-to-twin transfusion, the donor twin may develop oligohydramnios while the recipient twin develops polyhydramnios. Fetal or neonatal hydrops with anasarca, ascites, or pleural or pericardial effusions is also associated with polyhydramnios. CNS disease that compromises the brain's control of fetal swallowing can result in polyhydramnios.

### Antenatal Single Umbilical Artery

The number of umbilical vessels, 2 arteries and 1 vein, is usually assessed as part of the routine anatomic survey during the prenatal ultrasound. A single umbilical artery (SUA) is identified in 0.2% to 2% of fetuses. There is a known association of SUA with congenital anomalies, intrauterine growth restriction, and fetal demise. Cardiac anomalies, renal anomalies, and preterm birth

are significantly higher among infants with an SUA. SUAs diagnosed in the first trimester are highly associated with trisomy 18 and other chromosomal anomalies. Laterality has been examined to determine whether there may be an association for congenital anomalies. The absence of the left umbilical artery is more common than the right. An absent right umbilical artery has been associated with a higher incidence of genitourinary and gastrointestinal anomalies. A detailed anatomy scan including fetal echocardiogram is recommended for infants with an SUA. A recommended screening protocol for genitourinary malformations in patients with SUA should consist of routine prenatal ultrasound, a postnatal physical examination, a postnatal abdominal ultrasound, and possibly a postnatal VCUG. This screening likely would detect all significant urologic disease in a fetus or neonate.

### Antenatal Sex Determination

Although many families' primary interest in the prenatal ultrasound is to discover the sex of their infant, for the physician the prenatal ultrasound affords an opportunity to detect genitourinary anomalies. In some cases, congenital adrenal hyperplasia can be diagnosed with ultrasound by an initial finding of genital ambiguity. Treatment can be initiated prenatally to avoid further complications.

The CDC reports that the rate of hypospadias has increased dramatically in the last 2 decades, confirming similar findings in Europe. Hypospadias may lead to an incorrect prenatal gender assignment. After the first trimester, accuracy of sex determination via ultrasound is 99%; however, incorrect fetal sex determination may have significant emotional repercussions for the family. It has been associated with marital conflicts, domestic violence, negative perceptions of ultrasound, and a desire for reversal of tubal ligation.

### Antenatal Limb Anomalies

The frequency of limb anomalies is 6 in 10,000 with a higher occurrence in the upper limbs. Clubfoot or talipes equinovarus deformity is the most common musculoskeletal defect, followed by upper limb reduction abnormalities (Figure 97-1). Limb anomalies

detected early are often associated with serious congenital conditions.

The literature on prenatal diagnosis of common limb anomalies is extensive. Ermito et al. describe many of the upper limb anomalies that can be visualized via ultrasound, including clinodactyly, radial clubhand, terminal transverse limb defects (upper limb transverse deficiency is the most common), syndactyly, postaxial polydactyly (Ellis-van Creveld syndrome), and phocomelia. Detecting limb anomalies is useful for overall syndrome identification and making the family aware in advance of the delivery where possible so as not to be surprised.

Prenatal diagnosis of congenital clubfoot has been extensively studied. Glotzbecker et al. recently described a severity scale, with the more severely deformed foot having a higher level of prenatal accuracy. This can provide a higher degree of confidence in the prenatal diagnosis when counseling families. However, parents should be counseled that a clubfoot can still occur although it was not detected prenatally by ultrasound. In addition, there may be associated anomalies present that are not detected by the ultrasound. It is important to avoid terms such as "missed" or "misdiagnosis" when talking to parents. Ultrasound is also useful to detect skeletal dysplasias. These include diastrophic dysplasia, achondroplasia, thanatophoric dysplasia, Kniest, campomelic dysplasias, chondroectodermal dysplasia, and arthrogryposis congenita. Upper and lower limb deformities that result from amniotic band sequence (also referred to as amniotic deformity, adhesion, and mutilation [ADAM] sequence) are detectable by prenatal sonography, as are limb deficiencies that arise from hypoplasia or agenesis of 1 or more long bones. Three-dimensional ultrasound is a newer modality to visualize the infant in a more panoramic view. Accuracy of diagnosis is not 100%, but is more accurate if the diagnosis is a lethal condition.

### Antenatal Hydronephrosis and Pyelectasis

Antenatal hydronephrosis (ANH) is among the most common abnormalities detected on prenatal sonography and has a reported incidence of 1% to 5%. Etiologies of ANH include transient dilation of the collecting system, upper and lower urinary tract obstructive uropathy, and nonobstructive conditions such as vesicouterine reflux (VUR) and less commonly cystic kidney disease, congenital strictures, megaureters and prune belly syndrome (see Table 97-2). Pyelectasis, dilation of the renal pelvis, is a more common finding on prenatal sonography. The reported incidence of pyelectasis is 2% to 7%. Pyelectasis is most commonly caused by ureteropelvic junction obstruction (UPJO), VUR, posterior urethral valves, and ureteral obstruction. Less commonly, antenatal hydronephrosis may be associated with prune belly syndrome, VATER syndrome, solitary kidney, and renal mass. As the pregnancy progresses, pyelectasis can develop into hydronephrosis or resolve spontaneously. An association also exists between pyelectasis occurring later in gestation and Down syndrome.

Defining the severity of ANH can be challenging. At present, measurement of the anterior-to-posterior

**Figure 97-1** Prenatal ultrasound of a clubfoot.

**Table 97-2****Etiology of Antenatal Hydronephrosis**

ETIOLOGY	INCIDENCE
Transient hydronephrosis	41%–88%
UPJ obstruction	10%–30%
Vesicoureteric reflux (VUR)	10%–20%
Ureterovesical junction obstruction/ megaureters	5%–10%
Multicystic kidney disease	4%–6%
Posterior urethral valves/ureteral atresia	1%–2%
Ureterocele/ectopic ureter/duplex system	5%–7%

From Nguyen HT, Herndon CDA, Cooper C, et al. The Society for Fetal Urology consensus statement on the evaluation and management of antenatal hydronephrosis. *J Pediatr Urol.* 2010;6:212–231, with permission from Elsevier.

diameter (APD) of the renal pelvis is used to assess ANH in utero. Gestational age, maternal hydration status, and the degree of maternal bladder distention can affect the APD measurements. An APD greater than 15 mm is considered indicative of severe fetal hydronephrosis. Prenatal grading of ANH severity includes characterization of the hydronephrosis as mild, moderate, or severe, and specifies the extent of renal pelvis and calyces involvement (pelviectasis, pelvicaliectasis, caliectasis). Postnatally, a different grading system is used based on the appearance of the renal pelvis, calyces, and renal parenchyma. Oligohydramnios is an important factor in predicting the likelihood of postnatal pathology.

Wide variation can be found in the prenatal assessment and postnatal management of infants with ANH. A meta-analysis conducted to determine the risk of postnatal disease in infants with ANH found that the risk of VUR among infants born with ANH was 8.6%, nearly 9 times higher than the incidence found among infants without ANH. Infants born with severe ANH have a high risk (88.3%) of underlying genitourinary tract pathology. In comparison, infants with mild or moderate ANH have been shown to have lower rates of postnatal pathology; however, the rates of associated abnormalities remain highly significant at 11.9% and 45.1%, respectively. Transient hydronephrosis caused by renal pelvis or calyceal dilation resolves over time without intervention in most children. It is reported that most children with antenatal renal pelvic dilation less than 6 mm in the second trimester or less than 8 mm in the third trimester have transient hydronephrosis. The incidence of transient hydronephrosis decreases with increasing anterior-posterior diameter detected during the third trimester. Figure 97-2 is a prenatal ultrasound of severe hydronephrosis.

Infants with significant hydronephrosis are more often male and have evidence of left kidney involvement. Additional information garnered from the prenatal evaluation that informs the diagnostic and management considerations includes renal calyceal dilation, echogenicity of the kidneys, thinness of the renal parenchyma, presence of hydroureteronephrosis,

**Figure 97-2** Prenatal ultrasound of hydronephrosis.

bladder dilation, posterior urethral dilation, fetal gender, laterality of the involved kidney, and amniotic fluid volume. Oligohydramnios is associated with a poorer prognosis. Bladder distention or the presence of lower urinary tract obstruction suggests posterior urethral valves, VUR, or megacystis, particularly in a male fetus. The presence of prenatal renal dysplasia (renal cysts and hyperechoic renal parenchyma) can indicate poor kidney function. Renal cysts are highly specific for kidney dysplasia, whereas kidney hyperechogenicity is a more sensitive, but less specific, sign. Spontaneous urinary tract decompression can occur in infants with severe urethral obstruction, causing ascites or a perinephric urinoma.

The timing of the prenatal ultrasound is also important in predicting the importance of the findings. Infants with isolated ANH have varying degrees of renal pelvis or calyceal dilation, referred to as pelviectasis or pelvicaliectasis. Postnatal sonography is usually performed 5 to 7 days after the infant's birth to reevaluate the kidneys. At 5 days of age, 25% of newborns with ANH show no evidence of residual hydronephrosis. While half of the newborns with pelviectasis exhibit mild dilation, pelviectasis has resolved in 50% of babies with dilation on the initial postnatal renal sonogram.

Newborns with ANH should be thoroughly examined for the presence of other anomalies and assessed for adequate urine output. Postnatal evaluation and management remains controversial; there is significant variation in administration of antibiotic prophylaxis. Postnatal sonography performed within 48 hours of birth may underestimate the degree of hydronephrosis. Depending on the sonographic results, further evaluation may be indicated, including VCUG and nephrology and/or urology consultation. Initiating postnatal antibiotic prophylaxis to reduce the risk of infection before performing postnatal imaging to confirm the presence of associated VUR is controversial. Though recommendations regarding management of a first urinary tract infection in infants between 2 and 24 months have been recently published, the physician should be careful applying these recommendations to the newborn. The clinician

should consider consultation with a pediatric urologist to discuss optimal evaluation and management plans. Current recommendations include the following:

- Newborns with bilateral severe ANH ( $\geq 10$  mm in second trimester or  $\geq 15$  mm in third trimester) or a single kidney with any grade of hydronephrosis should undergo postnatal renal sonographic evaluation before hospital discharge.
- Newborns with any other grade of ANH should have a postnatal renal ultrasound examination performed within the first month of life (after the first 5 days of age).
- Newborns with persistent moderate to severe ANH should undergo a VCUG evaluation and functional studies as needed.
- Decisions regarding postnatal evaluation of newborns with mild persistent ANH or isolated ANH that resolves should be individualized based on the specific infant issues.
- Pyelectasis that resolves spontaneously before birth does not require postnatal evaluation.
- Newborns with persistent pyelectasis should have postnatal renal sonographic evaluation performed within the first month of life with additional evaluation (VCUG evaluation and functional studies) and antibiotic prophylaxis based on sonographic and clinical findings.

### Antenatal Identification of Central Nervous System Variants

Cerebral malformations occur in approximately 1% of live births and are the second most common congenital abnormality following congenital heart disease. Suspicion of a CNS abnormality requires a multidisciplinary evaluation. Testing may include evaluation for TORCH infections, screening and amniocentesis for karyotyping and microarray analysis. The corpus callosum becomes clearly visible by 20 weeks' gestation. Major sulci are identifiable from 26 weeks of development. The lateral ventricle is typically larger in male fetuses. Transabdominal or transvaginal sonography in mid-trimester allows for visualization of most cerebral and cerebellar structures. The addition of color Doppler flow imaging and 3D or 4D imaging enhances detection rates. Fetal magnetic resonance imaging (MRI) may be needed to enhance delineation of suspected CNS anomalies. Isolated mild to moderate ventriculomegaly, defined as a lateral ventricle that measures between 10 and 15 mm, is the most common nonspecific nervous system anomaly identified, with a reported incidence of 1.4 per 1,000 live births in low-risk populations. Ventriculomegaly and cysts of the choroid plexus and subependyma are prenatal sonographic findings with an uncertain significance that warrant postnatal evaluation and follow-up. Ventriculomegaly is the most common CNS abnormality identified on prenatal sonography. It is an excess of fluid in the lateral ventricles within the developing cerebrum. Figure 97-3 is a prenatal ultrasound with ventriculomegaly. The diagnosis is most often identified at a routine fetal anatomy scan, traditionally undertaken at 18 to 22 weeks' gestation. An estimated 70% to 85% of fetuses with ventriculomegaly have associated structural or chromosomal anomalies, including neural

**Figure 97-3** Prenatal ultrasound of ventriculomegaly.

tube defects, structural and cortical brain malformations, hemorrhage, and porencephaly. Clinical risk is further influenced by additional factors such as maternal age and the results of maternal serum markers for aneuploidy. Though some of these cases resolve spontaneously, serial exams should be undertaken to follow the course. One-third of infants with isolated ventriculomegaly have been found to subsequently exhibit developmental delay in comparison with over 84% of infants with ventriculomegaly and associated anomalies. Mild, isolated ventriculomegaly (15 mm or less) is associated with normal school-age outcomes. In contrast, unilateral isolated ventriculomegaly and asymmetric ventricles (suggestive of infarction or ischemic injury) are identified risk factors for behavioral and neuropsychiatric disorders.

Choroid plexus cysts are detected on prenatal sonography in approximately 1% of pregnancies and are associated in a small percentage of infants with aneuploidy; 40% to 50% of infants with trisomy 18 and 1.4% of babies born with Down syndrome have choroid cysts. The risk for aneuploidy is unrelated to the location (laterality), size, number, or complexity of the choroid plexus cysts, or whether the cysts spontaneously regress. Advanced maternal age increases the infant's risk as well. Many choroid plexus cysts regress by 28 weeks of gestation. A multidimensional assessment of developmental status, emotional regulation and social engagement, motor control and activity level under conditions of activation and inhibition, and autonomic regulation failed to reveal significant differences between children with a choroid plexus cyst detected prenatally and those without detection, as long as the karyotype was normal.

Subependymal cysts are thought to represent hemorrhagic-ischemic injury in a portion of the periventricular region of the brain. Infants born preterm exhibit associated neurodevelopmental sequelae. The true incidence of cranial sonographic abnormalities in term infants is unknown; however, approximately 8% of infants have evidence of ischemic injury. The short-term neurodevelopment of these infants seems comparable to that of infants without cranial sonographic

abnormalities at birth. The detection of neural tube defects (NTDs) during pregnancy has been increased through the combination of maternal serum and amniotic fluid alpha-feto protein (AFP) levels in conjunction with fetal anatomy scanning. Identification of “lemon” (scalloping of the frontal bone) and “banana” (hypoplastic cerebellum) signs on fetal sonography has increased detection rates to more than 90%. Neural tube defects may be diagnosed as early as 11 to 13 weeks. Open defects are more commonly associated with hydrocephalus and Arnold-Chiari II malformations. Spina bifida occulta or closed NTDs are less likely to be associated with hydrocephalus or other anomalies. Midline malformations, such as semilobar and lobar holoprosencephaly, can be diagnosed in the first trimester. Fetal MRI can augment 3D sonographic imaging to further characterize the abnormality. Partial or complete agenesis of the corpus callosum occurs in approximately 5 in 1,000 births and can also be identified by fetal imaging, optimally in the second trimester. Agenesis of the corpus callosum may be isolated or occur in conjunction with chromosomal defects, genetic syndromes, and metabolic and environmental disorders.

Recommendations include the following:

- After birth, head circumference must be measured accurately and plotted on percentile charts.
- Infants with prenatal cranial sonographic abnormalities require a postnatal cranial sonogram and a thorough physical examination for evidence of dysmorphism and other malformations.
- The prenatal information should be reviewed to ascertain whether the mother was evaluated prenatally for a TORCH infection (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex).
- Consultation with a pediatric neurologist and additional neuroimaging may be warranted based on the sonographic findings and clinical examination.
- Careful monitoring of the infant’s head growth and neurodevelopment is required.

### Antenatal Echogenic Intracardiac Focus

A bright echogenic focus within the cardiac ventricles was first described in 1987. Prevalence rates reported are between 0.5% and 20%. It is defined as a small structure within the fetal heart with similar or greater echogenicity compared to the surrounding bone. It may be related to increased mineralization or even calcification. This echogenic focus is usually in the vicinity of the papillary muscle, chordae tendinae, and atrioventricular valves. This is thought to be a normal finding in low-risk populations, although the presence of cardiac echogenic foci may be associated with trisomy 21 in high-risk pregnancies. Results from high-risk groups (advanced maternal age, abnormal biomarkers [triple or quad screening], prior affected offspring) suggest that isolated cardiac echogenic foci may be associated with a higher risk of fetal aneuploidy. When a mass is seen associated with a bright focus or calcification, a tumor such as a rhabdomyoma or teratoma should be considered. Cardiac echogenic foci usually regress with age, with most resolving by age 5. In low-risk pregnancies, isolated intracardiac

echogenic foci are not associated with impaired ventricular function, valvular disease, or childhood myocardial dysfunction. No specific postnatal follow-up assessment is required.

### Postnatal Evaluation of Lung Anomalies

Fetal lung masses that cause respiratory distress are reviewed in detail in Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn. Antenatally diagnosed lung lesions are most commonly congenital cystic adenomatoid malformations or bronchopulmonary sequestrations. Many echogenic fetal lung masses regress antenatally, whereas other lesions will enlarge in size. Postnatal evaluation of the asymptomatic infant with a history of an antenatal fetal lung mass should include chest radiograph and a computed tomographic (CT) scan. Residual lesions are often visible on CT scan despite apparent resolution on prenatal sonography.

Recommendations include the following:

- Thorough examination of the infant for evidence of respiratory compromise
- Postnatal chest radiographs and chest CT scan
- Pediatric surgical consultation and close follow-up

A defect in the fetal diaphragm causes CDH, which occurs 1 in 2,400 newborns. The number is likely higher if fetal losses and terminations are included. This defect is usually diagnosed prenatally via ultrasound. When a prenatal diagnosis is made, it is important for the pregnant woman to seek consultation at a tertiary center experienced in treating infants with CDH. Consultations with a pediatric general or cardiothoracic surgeon and neonatologist provide an opportunity to discuss prenatal and postnatal medical treatment options.

### Postnatal Evaluation of Intra-abdominal Fetal Echogenic Masses

Fetal echogenic lesions in the abdomen are common prenatal sonographic findings. Formulation of a presumptive diagnosis is based on a thorough evaluation of the lesion’s characteristics and structure, and on the presence of calcifications. Echogenic bowel is the most common echogenic mass in the fetal abdomen, identified in 1% of second-trimester fetuses that are evaluated. Spontaneous resolution occurs in 50% of affected infants. Echogenic bowel may be associated with fetal growth restriction. Differential diagnosis of echogenic bowel includes cystic fibrosis, chromosomal abnormalities, intra-amniotic bleeding, and congenital infection (cytomegalovirus, herpes). Prenatal detection of echogenic bowel, other echogenic masses, and/or intra-abdominal calcifications typically prompts a detailed review of the maternal history and assessment for additional findings. Evaluation may include genetic counseling and fetal karyotyping, viral studies, and parental testing for cystic fibrosis genes. Bowel echogenicity seen on a third-trimester sonogram is a common variant and reflects meconium in the intestine.

Intra-abdominal calcifications are often present in infants with meconium peritonitis caused by an intestinal perforation that develops in response to a vascular insult or cystic fibrosis. Enterolithiasis,

intraluminal calcified meconium, may occur in the presence of cloacal anomalies. Infants with isolated abdominal calcifications generally have a normal outcome. Other sites of calcification include the liver, where calcifications may be associated with congenital viral infections (TORCH), or more rarely in the presence of hepatoblastoma or metastatic neuroblastoma. Fetal gallstones and gallbladder sludge may be detected after 28 weeks' gestation on sonography. Often fetal gallstones are an incidental finding during a sonogram performed for another indication. Postnatal sonography may be indicated to confirm resolution. Noncalcified lesions may also be detected on fetal abdominal sonography. These lesions include hemangioma, hamartoma, enteric duplication cysts, adrenal lesions (hemorrhage, neuroblastoma), subdiaphragmatic extrapulmonary sequestration, and mesoblastic nephroma. Neuroblastomas are the most common adrenal neoplasm typically identified late in gestation, as a solid, usually right-sided mass with cystic components that is displacing the kidney. Spontaneous regression occurs in up to 40% of affected patients, though calcifications may persist. Mesoblastic nephroma is the most common primary renal tumor presenting in the first month of life. Although it is benign, affected infants often develop heart failure and require early nephrectomy.

Recommendations for postnatal evaluation of suspected meconium peritonitis include the following:

- Postnatal abdominal radiography with additional upper and lower gastrointestinal tract studies may be performed to evaluate for perforation.
- Consider surgical consultation to assist in evaluation of the infant.
- If the radiographic studies are normal and the infant passes meconium, then further evaluation is not required.
- Consider screening for cystic fibrosis if this testing was not performed prenatally.

Dilated bowel loops are another common finding on second- and third-trimester prenatal sonography. The fetal bowel can be altered by a number of pathologic processes. The most common pathology is a bowel dilatation characteristically recognized as 1 or more tubular structures within the fetal abdomen. Bowel dilatation is caused by obstruction that may be either mechanical (atresia or stenosis, malrotation, volvulus, aganglionosis) or functional (microcystis-megacolon intestinal hypoperistalsis syndrome). Normal large intestine may be misidentified as dilated small bowel. The extent of postnatal evaluation of infants with a history of dilated fetal bowel loops depends on the clinical condition of the infant at delivery and the specific sonographic findings on third trimester scanning (see Box 97-1). A well-appearing infant with high suspicion criteria should have an abdominal radiograph taken within the first 4 to 6 hours of life. The infant, if healthy and hemodynamically stable without transitional issues, may be allowed to remain with the mother for the first hour for skin-to-skin care and the first breastfeeding. The initial colostrum intake is typically no more than 1 to 2 mL. An infant with abdominal distention evident at

### BOX 97-1 Antenatal Sonographic High Suspicion Criteria for Intestinal Obstruction

**Small bowel** (smooth internal wall without haustral folds) >10 mm in third trimester (>28 weeks' gestation) at the time of the study with 1 of the following:

1. Hyperperistalsis
2. Polyhydramnios
3. Echogenic bowel
4. Increase in dilation over time or loop >20 mm in diameter
5. Whirlpool sign (suspicious for volvulus) Or, **dilated large intestine** (>20 mm)

delivery, respiratory distress, or transitional difficulty should be immediately transferred to the neonatal unit for stabilization, surgical consultation, evaluation, and management. Second-trimester findings that have resolved on the third trimester follow-up do not warrant radiographic imaging after delivery.

### Fetal Ovarian Cysts

Ovarian cysts are the most common cystic abdominal mass in newborn girls; however, a palpable cystic mass in the newborn is more likely to be of renal than ovarian origin. The incidence of clinically significant ovarian cysts diagnosed antenatally is approximately 1 in 2,500. Because of the hormonal influence at birth (fetal gonadotropins, maternal estrogen, and placental human chorionic gonadotropin), 98% of newborn girls may have ovarian cysts on ultrasound. Under the influence of these hormones, follicular cysts develop and can be detected as early as 28 to 32 weeks of gestation. Cysts are also more common in conditions such as maternal diabetes mellitus where there is an increased production of human chorionic gonadotropin (hCG) by the placenta. During the last trimester of pregnancy, there is a fall in fetal follicular stimulating hormone (FSH) and luteinizing hormone (LH), with a subsequent postnatal rise in these hormones, possibly in response to the drop in maternal hCG and estrogen levels at birth. Most ovarian cysts resolve spontaneously because of this drop in gonadotropin levels.

The cysts may achieve considerable size, reaching up to 5 cm. They may be unilateral or bilateral, unilocular or multilocular. A tendency exists for cysts less than 3 cm in size to regress near term or in the early neonatal period. Serial ultrasound of fetal ovarian cysts is indicated because approximately 35% of patients develop symptoms of torsion or rupture of the cyst, either prenatally or in the postnatal period. Torsion of cyst is suspected when changes on ultrasound findings occur that are consistent with intracystic hemorrhage. This circumstance is an indication for immediate surgical intervention. Diagnosis is confirmed by a postnatal abdominal ultrasound (Figure 97-4). On ultrasound, cysts may appear as

**Figure 97-4** A. Ovarian cyst. Plain abdominal radiograph shows a mass effect in the left abdomen with displacement of the bowel loops. B. Ovarian cyst. Postnatal abdominal ultrasound shows a large cystic mass in the ovary.

simple or complex with debris, internal echoes, or solid elements in them.

Recommendations include the following:

- Postnatal evaluation should consist of a thorough abdominal examination for a palpable mass; abdominal sonographic evaluation is also recommended.
- Surgical consultation and follow-up are required if an ovarian cyst is identified, particularly if evidence is found of a large complex cyst, hemorrhage, or torsion, or if the lesion is causing bowel obstruction.

### Antenatal Gastrointestinal Findings

A history of polyhydramnios should alert the physician to suspect a proximal intestinal obstruction, such as tracheoesophageal fistula, or esophageal, duodenal, or jejunoileal atresia. A thorough physical examination should be performed with emphasis on inspection and palpation of the abdomen and perineum and assessment of the infant for evidence of other anomalies.

Newborns with tracheoesophageal fistula or esophageal atresia often have copious secretions after birth. This can be easily diagnosed with a radiograph after placing an orogastric tube. Duodenal and jejunoileal atresias often exhibit symptoms in the immediate postnatal period with the onset of vomiting, with or without prior feeding. Duodenal atresia occurs in 1 in 5,000 live births; 25% of affected infants have Down syndrome. Neonates with duodenal atresia develop bilious vomiting in the first hours after birth and may not exhibit abdominal distention. A *double bubble* is the characteristic finding on abdominal radiography. Jejunoileal atresias are caused by intrauterine vascular accidents and occur in 1 in 3,000 live births. Neonates with jejunoileal atresia also are typically symptomatic

within the first day of life, exhibiting vomiting and abdominal distention. Abdominal radiographs demonstrate air-fluid levels and dilated bowel.

Gastroschisis is a prenatal evisceration of the fetal bowel through a defect in the abdominal wall. It occurs in 1 in 4,000 live births. Common associated anomalies are gastrointestinal (intestinal atresia and malrotation). Sonographic findings include small and large bowel loops outside the abdominal cavity and in the amniotic fluid. The smaller the defect, the greater propensity to have intestinal blood flow restriction, and more damage can be expected, but with prompt surgical intervention the prognosis is excellent. In many cases polyhydramnios develops as a result of the intestinal obstruction, and intrauterine growth restriction coexists. Surgical intervention, close monitoring and correction of fluid and electrolyte abnormalities, and administration of broad-spectrum antibiotics are warranted.

Omphalocele is another defect in the abdominal wall often detected prenatally by ultrasound. Many babies with this condition also have other birth defects. Small defects are more common (1:5,000) than giant omphaloceles (1:10,000). The size of the defect and the presence of comorbidities affect the outcome of these infants. Figure 97-5 is a prenatal ultrasound of an omphalocele.

For a full discussion of related topics, see Chapter 108, Surgical Emergencies of the Chest and Abdomen in the Newborn.

### Neonatal Gastrointestinal Anomalies Causing Early Serious Illness

Bowel obstruction may be caused by intestinal atresias, malrotation with midgut volvulus, and Hirschsprung disease. Vomiting during the neonatal period should

**Figure 97-5** Prenatal ultrasound of an omphalocele.

alert the physician to a potential intestinal anomaly. Although initial symptoms may be nonspecific, the onset of bilious vomiting constitutes a medical emergency that warrants immediate assessment and intervention. Review of prenatal sonography may help inform the diagnosis.

Newborns with a malrotation and midgut volvulus exhibit bilious emesis and poor feeding and may rapidly develop lethargy and shock. In addition to placement of a nasogastric tube and initiation of intravenous fluid resuscitation and antibiotic therapy, abdominal radiographs and an upper gastrointestinal series must be obtained immediately. Concurrent surgical consultation and arrangements for transfer to a neonatal or pediatric critical care unit are paramount.

Newborns with esophageal atresia and tracheoesophageal fistula often have a prenatal history of polyhydramnios. These babies may exhibit symptoms shortly after birth, particularly during the first attempt at feeding. Placement of a nasogastric tube before obtaining a radiograph of the chest and abdomen will show the feeding tube coiled in the upper esophageal pouch. If air is present in the stomach, then the infant has an associated tracheoesophageal fistula.

The infant with Hirschsprung disease typically exhibits constipation or failure to pass meconium in the first 24 hours of life. Affected infants exhibit poor feeding, vomiting, progressive abdominal distention, irritability, and bloody stools. Stabilization including fluid resuscitation and broad-spectrum antibiotic administration should be performed in conjunction with obtaining imaging studies, transfer to a neonatal or critical care unit, and surgical consultation. Abdominal radiographs typically demonstrate a markedly dilated colon. The diagnosis is confirmed with a rectal biopsy.

Bowel obstruction may also occur as a result of meconium ileus, meconium plug syndrome, or a small left (micro) colon. Meconium ileus occurs in 10% to 20% of infants with cystic fibrosis (CF) and may be the earliest manifestation of CF. Enemas are used to decompress the intestinal obstruction. Perforation and pseudocyst formation may complicate the infant's course. The presence of calcifications on abdominal imaging indicates an intrauterine perforation occurred. Newborns with meconium plug syndrome are otherwise healthy neonates with plugs of meconium in the colon. Meconium plug syndrome is not associated with CF but occurs in

infants with intestinal dysmotility—infants of diabetic or preeclampsia mothers, those exposed in utero to magnesium sulfate, and those who are preterm with sepsis or hypothyroidism. Small left colon syndrome occurs in infants of diabetic mothers. Maternal lithium use is also associated with small left colon syndrome.

### Summary

As technology continues to improve, prenatal ultrasound assessments are becoming more informative. Although ultrasonography has vastly improved the field of prenatal medicine, families and caretakers alike should keep in mind that it is a screening test and not as definitive as chorionic villi sampling or amniocentesis for diagnosing aneuploidy. When there is an abnormal prenatal ultrasound finding, a timely consultation with a specialist is recommended.

We acknowledge all of the ultrasound contributions shown in figures, contributed by Dr. Pe'er Dar, Associate Professor of Obstetrics & Gynecology and Director of Fetal Medicine and OBGYN Ultrasound, Department of Obstetrics & Gynecology and Women's Health, Montefiore Medical Center, Albert Einstein College of Medicine.

# Neonatal Medical Conditions

### Chapter 98

## ABNORMALITIES OF FETAL GROWTH

Suhas M. Nafday, MD, MRCP(Ire), DCH

Fetal growth is determined by fetal genotype and, to a large extent, by the uterine environment. The in utero environment is predominantly influenced by maternal genetics, the size of the mother, the capacity of the placenta to provide nutrients to the fetus, and, to a modest degree, paternal genetics. Although several genes have been described as maternally or paternally imprinted, 2 growth disorders, Beckwith-Wiedemann syndrome (macrosomia) and Russell-Silver syndrome (fetal malnutrition), represent well-characterized phenotypes that arise as a consequence of disrupted imprinting. Two protein products of genes, such as insulin-like growth factors I and II, play a specific role in the growth of trophoblastic cells, which form the placenta. Abnormalities in genes affecting growth may result in adverse effects. Various factors affecting fetal growth are listed in Table 98-1.

### INTRAUTERINE GROWTH RESTRICTION

Intrauterine growth restriction (IUGR), or fetal growth restriction, is a common complication of pregnancy with significant short- and long-term sequelae that reach out to adulthood. IUGR is the second leading cause of perinatal mortality, with a 10-fold increase in rates for all cases of IUGR compared with normally grown fetuses after exclusion of aneuploidy and anomalous fetuses. Up to 50% of survivors will experience intrapartum asphyxia, which adds to the already increased risk for end-organ injury.

At present, many physicians do not distinguish between the terms *small for gestational age* (SGA) and IUGR. However, these 2 clinical entities are not the same. SGA newborns traditionally have been defined as those whose birth weights are more than 2 standard deviations below the mean or less than the 10th percentile of population-based weight data obtained from newborns at the same gestational age. Conversely, a newborn with IUGR has not reached genetic growth potential as a result of an insult that occurred in utero. An IUGR fetus may or may not be SGA, but IUGR always implies a pathologic process. The decreased fetal growth rate in IUGR is an adaptation to an unfavorable intrauterine environment

**Table 98-1** Factors Affecting Fetal Growth

FACTOR	COMMENT
Fetal genetic potential	Specific genes must be expressed for fetal and placental growth.
Maternal size and uterine size	Fetal growth constraint from the maternal environment is a physiologic process that includes the maternal-specific capacity of uterine size, placental implantation surface area of the uterus, and uterine circulation, which together support the growth of the placenta and its function. <sup>a</sup>
Patterns of gestational age	Length of gestation is proportional to fetal weight but is more strongly correlated to neural growth.
Fetal nutrient uptake and metabolism; regulation of fetal growth	Decreased rates of fetal growth represent an adaptation to inadequate nutrient supply (intrauterine growth restriction).
Maternal nutrition	Only severe starvation limits fetal growth; growth may be limited by 10% to 20%.
Placenta	True placental hormones, particularly placental lactogen, play an important role in fetal growth. Placental insufficiency leads to fetal growth restriction. Placental size and fetal size are directly related. <sup>b</sup>
Glucose, amino acids, and fat transport across placenta	Intrauterine growth-restricted infants have lower glucose levels. Amino acids and energy supply are important for fetal growth. Fat accumulation occurs predominantly in the third trimester.
Maternal and fetal endocrine regulation	Maternal growth hormone and human placental lactogen increase during pregnancy, which induces insulin resistance and increased facilitated glucose transport to fetus. In infants of diabetic mothers, increased supply of glucose stimulates fetal insulin and promotes fetal adiposity (macrosomia).

<sup>b</sup>Molteni RA, Stys SJ, Battaglia FC. Relationship of fetal and placental weight in human beings: fetal/placental weight ratio at various gestational ages and birth weight. *J Reprod Med*. 1978;21:327-334

and may cause permanent alterations in metabolism, growth, and development.

IUGR is commonly defined as birth weight under the 10th percentile on intrauterine growth curves. Some perinatologists have defined IUGR as birth weight lower than 2 standard deviations below the mean, which roughly corresponds to less than the third percentile on intrauterine growth curves. Low birth weight is defined by the World Health Organization as a birth weight below 2,500 g, but this does not consider gestational age. Other weight-based definitions include *very low birth weight* (<1,500 g), *extremely low birth weight* (<1,000 g), and, more recently, *micropremie* (<750 g).

However, some infants are constitutionally small. These infants have no increased obstetric or neonatal risks. Availability of continuous fetal growth curves, developed from information gathered by ultrasound, has helped in diagnosing IUGR earlier. Race and ethnicity also play an important role. The growth curves should ideally be tailored to the patient population and geographic region.

Another concept relates to *symmetrical* (proportionately small) versus *asymmetrical* (relative head-sparing) growth restriction. Symmetrical IUGR is likely to result from an early fetal insult caused by chemical exposure (eg, nicotine from cigarette smoking), viral infection, or inherent developmental abnormalities caused by aneuploidy, whereas asymmetrical IUGR is likely to be the result of uteroplacental insufficiency, with preferential shunting of fetal blood to the brain. IUGR is associated with a significantly higher stillbirth rate and infant mortality rate in preterm, term, and postterm infants.

Another subset of newborns with IUGR who are born preterm is at a significant risk for hypoglycemia. The risk factors that predispose preterm IUGR infants to hypoglycemia are reduced glycogen and fat stores, increased consumption of glucose, hyperinsulinism, immaturity of hepatic enzymes, reduced

expression of glucose-6-phosphatase, reduced ketogenesis, and failure of counterregulation. These infants require regular monitoring of blood glucose levels even after full feeds have been established.

Recent epidemiologic studies have shown that the “metabolic syndrome,” including obesity, insulin resistance, diabetes, and cardiovascular disease, is more common among adults who were growth restricted at birth.

### Causes of Fetal Malnutrition and Intrauterine Growth Restriction

Fetal growth is a complex, dynamic process controlled by a wide range of factors of maternal, placental, and fetal origin. In early fetal life, the major determinant of growth is the fetal genome; however, later in pregnancy, environmental, nutritional, and hormonal influences become increasingly important. The known clinical, genetic, and environmental factors associated with IUGR are listed in Table 98-2.

### Preventive Strategies

Strategies to predict and prevent the recurrence of IUGR are critical in perinatal management. Effective interventions for prevention of recurrent fetal growth restriction may include a reproductive plan for spacing of pregnancies, optimization of maternal medical conditions, smoking cessation, accurate dating by first-trimester sonography and monitoring of fetal growth with serial sonograms, and low-dose aspirin (80–160 mg) started before 20 weeks. In women with nutritional deficiencies, optimizing caloric intake with low-protein (<25%) supplementation of 500 to 1,000 calories may prevent recurrent fetal growth restriction. In women living in areas endemic for malaria, antimalarial prophylaxis diminishes risk for recurrent fetal growth restriction.

It is important to be aware that maternal environmental exposures can be preconceptional or “noncurrent” fetal exposures that result from maternal

**Table 98-2**

**Clinical, Genetic, and Environmental Factors Associated With Intrauterine Growth Restriction**

FETAL	MATERNAL	PLACENTAL
Chromosomal abnormality	Substance abuse	Partial placental separation
Aneuploidy	Smoking	Uteroplacental insufficiency
Multifactorial congenital malformations	Alcohol	Unexplained elevated alpha
Cardiovascular abnormalities	Drugs: amphetamines, corticosteroids,	feto-protein, preeclampsia
Renal agenesis	heroin, hydantoin, propranolol,	Placental infarction
Multiple fetus pregnancy	warfarin	Placenta previa
Infection	Chronic disease	Multiple gestation, twin-to-twin transfusion
Cytomegalovirus	Cyanotic heart disease, cystic fibrosis,	Small placenta
Toxoplasmosis	asthma, renal disease, sickle cell disease,	Chronic vascular disease
Herpes simplex	lupus, inflammatory bowel disease,	
Rubella	advanced diabetes, hyper thyroidism	
Malaria	Constitutionally small mother	
Aberrant genomic imprinting	Lack of second-trimester weight gain	
Uniparental disomy	High-altitude pregnancy (hypoxia)	
Epimutations	Malnutrition	

Derived from Peebles DM. Fetal consequences of chronic substrate deprivation. *Semin Fetal Neonatal Med.* 2004;9:379–386.

excretion or mobilization of chemicals (lead). Additionally, exposures should be assessed for the father as well (even as a possible “paraoccupational” exposure whereby the father may have residual chemicals on clothing that a woman may be exposed to).

### Timing of Delivery

Close collaboration between obstetricians and neonatologists is essential for proper care of the growth-restricted fetus. When persistent fetal growth restriction is detected, antepartum surveillance should always include weekly serial Doppler studies of the umbilical artery because this testing has been associated with a significant reduction in perinatal mortality in women with fetal growth-restricted infants.

A joint decision on the appropriate timing of delivery is made based on the risk for fetal compromise compared with that of neonatal morbidity. The management of a fetus with growth restriction must include a balance of the risks of intrauterine chronic hypoxia with those of preterm delivery. Delivery may be indicated if the fetal growth-restricted infant has absent or reversed diastolic flow in the umbilical artery Doppler at 30 to 32 weeks (30%–32% weeks) or later, especially after steroids for fetal lung maturity have already been given if the fetus is less than 34 weeks’ gestation.

### Management in the Delivery Room

Competent personnel trained in neonatal assessment and resuscitation should be present at the time of delivery. Care should be taken to prevent hypothermia. Assuring an optimal environmental ambient air temperature and covering the infant with plastic wrap and a hat soon after delivery maintain core body temperature well. In the event of a stillborn fetus, karyotyping, serologic testing for congenital infection, and complete autopsy should be performed. The placenta should be examined for the presence of infarcts and gross abnormalities and sent for histopathologic evaluation. Careful evaluation of the placenta at the gross and microscopic level may aid in either confirming or elucidating the cause for fetal growth restriction.

Perinatal hypoxia occurs with increased frequency among SGA infants, particularly those who have severe IUGR, which may cause fetal death or perinatal compromise. The rate of cesarean delivery is increased, and the need for resuscitation is frequent.

### Neonatal Management

Newborns with IUGR who have symptoms that result from respiratory distress, hypoglycemia, or polycythemia or who require resuscitation should be admitted to the neonatal intensive care unit. Asymptomatic newborns with IUGR of less than 35 weeks’ gestation or who weigh less than 1,800 g at birth should also be admitted to the neonatal intensive care unit for management.

### Examination of the Neonate

On physical examination, the skin is often dry, rough, desquamated, wrinkled, and at times covered in meconium. The skin may look plethoric, or the newborn may look pale in the presence of peripheral vasoconstriction.

The neonate may seem more mature as a result of a reduced amount of vernix caseosa. Fingernails may be long. The newborn is often alert looking and jittery, even without hypoglycemia or hypocalcemia. Cranial sutures may seem wide, with large fontanels. The umbilical cord is usually thin and can be stained yellow or green if meconium is passed in utero. Newborns can be hyperexcitable and exhibit aberrations in muscle tone. The Moro reflex may be exaggerated, with more extension and abduction. However, newborns with severe IUGR may be floppy because they become easily exhausted when they are handled. Severe symmetrical IUGR neonates should be checked for chromosomal abnormalities and evidence of any intrauterine infection (skin rash, hepatosplenomegaly, and ocular abnormalities such as cloudy cornea, cataract, or chorioretinitis).

Gestational assessment may be affected by the presence of many creases on the sole of the foot, small breast nodules, less well-formed ear cartilage, and less fat on female genitalia. The IUGR process does not greatly affect the neurologic assessment. The weight, length, and head circumference should be recorded. In addition, the ponderal index (PI) should be calculated as follows:

$$PI = \frac{\text{weight (g)} \times 100}{\text{crown-heel length (cm)}^3}$$

PI at lower than the tenth percentile reflects fetal malnutrition; PI at lower than the 3rd percentile indicates severe wasting. In cases of asymmetrical growth restriction, birth weight and occasionally length are less than the 10th percentile, but head circumference is preserved. The neonate will have a low ponderal index. Growth rates of adipose tissue and skeletal muscle are less than normal, although bone and probably brain growth are not. In cases of symmetrical growth restriction, a proportionate decrease in weight, length, and head circumference is present; the ponderal index will be normal. Combined IUGR shares features of both asymmetrical and symmetrical IUGR. Skeletal shortening and some reduction in soft tissue mass are seen. Causes include severe maternal disease from the first trimester of pregnancy, skeletal dysplasia, and metabolic bone disease. In dysmorphic IUGR, infants have disproportionately sized head, trunk, and limbs as a result of congenital abnormalities.

### Evaluation of the Neonate

Initial evaluation and stabilization should include preventing stress from the cold and observing the neonate for complications. If congenital infection is suspected, or if dysmorphic features are present, then appropriate evaluation should be undertaken, including laboratory testing for TORCH infections (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) urine for cytomegalovirus, and genetic assessment. Temperature should be monitored every 30 minutes until stable for 2 hours, then at least every 4 hours. The infant should be kept warm with bundling, and a hat should cover the head to avoid heat loss.

Blood glucose should be monitored within the first 1 to 2 hours of life by capillary glucose measurement, even if the child is asymptomatic. Early feedings,

within the first hour, including breastfeeding, should be encouraged to prevent hypoglycemia in newborns who are vigorous at birth. In the presence of asymptomatic borderline hypoglycemia (25–40 mg/dL or 1.39–2.22 mmol/L), the infant should be nursed frequently. Formula supplementation may be necessary until adequate mother's milk is available. Symptomatic newborns who are being exclusively breastfed may require intravenous glucose supplementation.

In the well-appearing SGA infant, hemoglobin level or hematocrit level should be measured at 6 to 8 hours of life by free-flowing venipuncture to evaluate for polycythemia. A hematocrit value of more than 65% or a venous hemoglobin concentration in excess of 22.0 g/dL indicates polycythemia. In the symptomatic infant, the timing of the initial hematocrit sampling should be determined by clinical signs.

### **PATHOPHYSIOLOGIC FEATURES AND MANAGEMENT OF PROBLEMS ASSOCIATED WITH GROWTH-AFFECTED NEONATES**

Infants who are SGA or IUGR may experience various problems that require different degrees of support based on their metabolism. Table 98-3 defines the most common problems and describes their management.

#### **Nutritional Management and Follow-up**

SGA infants have a relatively increased energy requirement caused by low muscle mass and fat content and metabolically active organs. Thus, feeding them aggressively seems logical so that they can catch up in growth. Clinically, this strategy seems to work in mild to moderate growth restriction, with the anticipation of catch-up growth by providing high caloric and protein administration. However, in the severely affected infant, the intrauterine environment may have altered organ and endocrine development, placing the infant at risk for later complications from hypertension, type 2 diabetes, and lipid abnormalities. Thus, in severe IUGR infants, rapid catch-up growth with high caloric intakes may not be advisable. Animal studies of fetal IUGR caused by maternal protein restriction demonstrated a shortened life span, particularly in male infants, when a catch-up strategy of markedly increased protein intake was administered after birth. Long-term clinical trials are needed to resolve this issue.

Given the risk for some degree of in utero intestinal ischemia in IUGR infants, it is unwise to tube feed the term growth-restricted infant. For the most part, feed advancement should use nipple feeds. Tube feeds can be used to advance feeds cautiously in the growth-restricted late preterm infant.

Fewtrell et al randomized 199 term SGA infants to receive either a 22 kcal/oz enriched formula (EF) or standard term formula. The EF group had better length and head circumference gains than the control group, with the largest benefit seen in females. No differences in weight were noted. Breastfed infants had slightly greater gains in weight and head circumference than the term formula-fed group, but these differences disappeared when confounding factors were accounted for. It is unclear whether catch-up growth

is beneficial or detrimental to long-term outcomes; therefore, a definitive recommendation cannot be made. However, it is worth noting that breastfed infants have high ketone body levels when blood sugar levels are low, and it is likely that these alternative fuels protect them from neurologic injury. Formula feeding is associated with lower ketone body levels.

#### **Outcomes of Growth-Restricted Infants**

Growth-restricted infants have a higher incidence of sudden infant death syndrome (SIDS), increased perinatal mortality rates, more frequent hospitalizations including for serious respiratory infections, increased incidence of neurologic disorders, and other morbidities requiring follow-up.

Growth and development depend on the degree of insult in utero and on the cause of growth restriction. Infants who are small as a result of family disposition will likely experience normal growth. Infants who are symmetrically growth restricted are not likely to catch up, but asymmetrical IUGR infants have a reasonable chance of normal growth and development.

Infants with a small head circumference along with growth restriction have associated poor neurologic and psychological outcomes, especially if the catch-up growth in head circumference has not occurred by 8 months of life. The prognosis for preterm SGA infants is relatively poor, especially preterm infants whose brain growth failure occurred before 26 weeks' gestation. In general, subnormal intellectual outcomes are more common among preterm SGA infants than term SGA infants. SGA infants may not exhibit delay in bone development, puberty, or sexual maturation at adolescence, although they may be shorter and lighter and have smaller heads.

IUGR infants with major chromosomal disorders have an extremely high incidence of handicap. Infants with congenital rubella or cytomegalovirus infection with microcephaly have poor outcomes, with a disability rate of more than 50%. Socioeconomic class significantly influences the school performance of children with IUGR: children from higher socioeconomic classes score better than those from low socioeconomic classes on achievement tests.

Interest in the short-term and long-term consequences of fetal growth restriction on cardiovascular, neurologic, and lung functions is increasing. Catch-up growth is potentially beneficial in the short term, but it may be detrimental to long-term fitness and survival. Adults who experienced severe growth restriction in utero have an increased incidence of hypertension, insulin resistance, type 2 diabetes, lifelong alterations in growth and development, obesity, and possibility of the development of metabolic syndrome.

#### **Key Points**

- Close collaboration between obstetricians and health professionals caring for neonates is essential for proper care of the neonate with IUGR, especially with the timing of delivery.
- Prenatal corticosteroid therapy remains effective and safe in preterm labor in the presence of IUGR.
- Delivery may be indicated if the fetal growth-restricted infant has absent or reversed diastolic

Reprinted with permission.

flow in the umbilical artery Doppler at 30 to 32 or more weeks' gestation, especially after antenatal steroid administration to promote fetal lung maturity, if less than 34 weeks' gestation.

- The cause of small size at birth carries great prognostic value.
- Close monitoring of temperature, glucose, and hematocrit is important for management. Blood glucose should be closely monitored even after full feeds have been established.
- Early feeding of these newborns should be encouraged to prevent hypoglycemia. In the event of asymptomatic hypoglycemia, breastfeeding infants

should nurse frequently. Formula supplementation may be necessary until the mother's milk volume has been established.

- Cautious advancement of feeds is recommended in preterm IUGR infants.
- IUGR is associated with significantly higher rates of stillbirth, mortality, and SIDS.
- Rapid catch-up growth is potentially beneficial in the short term, but it may be detrimental to long-term fitness and survival with the possibility of an increased incidence of hypertension, insulin resistance, type 2 diabetes, and obesity, and a possibility of the development of metabolic syndrome.

# **LARGE-FOR-GESTATIONAL-AGE INFANTS AND INFANTS OF DIABETIC MOTHERS**

## **Large for Gestational Age**

At the other end of the spectrum of fetal growth abnormalities are newborns who are large for gestational age (LGA). The risk to the LGA baby is not so much antepartum hypoxemia and acidosis as the problem of prolonged labor and intrapartum trauma. LGA infants may have associated metabolic abnormalities (hypoglycemia, hypocalcemia), traumatic birth injuries, polycythemia, hyperviscosity, and hyperbilirubinemia, as well as the possibility of various congenital anomalies. Newborns are considered to be LGA if they weigh more than the 90th percentile for their gestational age or if they weigh more than 4,000 g (8 lb, 13 oz). *Macrosomia* is a clinical term describing excessive weight for gestational age; it results from increased adiposity caused by adipocyte hyperplasia and hypertrophy. Infants whose birth weight exceeds the 97th percentile (>4,500 g, or 9 lb, 4 oz) are at greater risk for neonatal morbidity, with babies weighing more than 5,000 g (11 lb) at highest risk for death. A subpopulation of LGA infants born to mothers with diabetes mellitus (before or during pregnancy) has various abnormalities. These infants are labeled under a syndrome known as *infant of diabetic mother* (IDM). Some of the IDMs born to mothers with long-standing diabetes mellitus and vascular disease may be SGA.

Most macrosomic babies are not associated with diabetes but rather with large mothers. LGA infants can result from being born to obese mothers (constitutional), from gestations longer than 42 weeks (postmaturity), or as the result of overstimulation of growth in utero. Additional risk factors include maternal weight gain during pregnancy, multiparity, a male fetus, and ethnicity. Infants of mothers with pregestational diabetes mellitus or gestational diabetes are exposed to high blood sugar during fetal development, or they may develop high circulating insulin levels and may therefore grow excessively. Women with gestational diabetes with glucose tolerance during late pregnancy (a positive glucose challenge test with a negative glucose tolerance test) may remain undiagnosed and may deliver a macrosomic infant with greater perinatal complications. Infants with Beckwith-Wiedemann syndrome and other genetic disorders with early excessive fetal growth, as well as infants with erythroblastosis fetalis, may exhibit as LGA with or without hyperinsulinism.

## **Infants of Diabetic Mothers**

Although many IDMs have an uneventful perinatal course, other such infants have an increased risk for complications. Better management of diabetes mellitus during pregnancy has led to a marked improvement in perinatal morbidity and mortality; however, opportunities for improvement in various outcomes remain. Perinatal mortality varies directly with severity of maternal diabetes, as judged by 2 commonly used maternal classification schema: White's revised classification of diabetes in pregnancy, based on duration of diabetes and presence of vascular complications (Table 98-4), and Pedersen's Prognostically Bad Signs in Pregnancy

Table 98-4	White's Classification During Pregnancy
CLASSIFICATION	DESCRIPTION
Gestational diabetes	Abnormal glucose tolerance test, but euglycemia maintained by diet alone; if diet alone insufficient, insulin required
Class A	Diet alone, any duration or age at onset
Class B	Age at onset, >20 yr; duration, <10 yr
Class C	Age at onset, 10–19 yr; duration, 10–19 yr
Class D	Age at onset, <10 yr; duration, >20 yr; background retinopathy or hypertension (not preeclampsia)
Class R	Proliferative retinopathy or vitreous hemorrhage
Class F	Nephropathy, with <500 mg/dL proteinuria
Class RF	Criteria for both classes R and F coexist
Class H	Arteriosclerotic heart disease clinically evident
Class T	Prior renal transplantation

Reprinted from Cowett RM. The infant of diabetic mother. *NeoReviews*. 2002;3:e173–e189.

classification, which includes complications of current pregnancy, that is, the presence of chemical pyelonephritis, precoma or severe acidosis, toxemia, and pregnant diabetic women who are noncompliant with recommended care. Preeclampsia often complicates diabetic pregnancy and results in higher incidence of preterm delivery with consequent increased morbidity and mortality.

## **Pathophysiologic Features**

Although no single pathogenetic mechanism has been clearly identified to explain the diverse problems seen in IDMs, many of the effects can be attributed to maternal metabolic control. Pedersen's maternal hyperglycemia–fetal hyperinsulinism hypothesis recognized that maternal hyperglycemia resulted in fetal hyperglycemia, which stimulates the fetal pancreas, resulting in islet cell hypertrophy and  $\beta$ -cell hyperplasia with increased insulin availability. Neonatal macrosomia results from increased adiposity (hyperplasia and hypertrophy) and increased liver and skeletal mass as a result of insulin-stimulated fetal growth. The acceleration in growth begins about the 25th to 28th week of gestation, which explains why very preterm IDMs do not exhibit macrosomia.

After delivery, the neonate develops neonatal hypoglycemia as a result of the absence of continuous glucose supply across the placenta. The presence of increased C peptide and reactive immunoinsulin concentrations with hypoglycemia suggests that the control of maternal hyperglycemia in the third trimester may decrease the incidence of neonatal hypoglycemia. Other factors that

**BOX 98-1 Components for Hyperinsulinism in Infants of Diabetic Mothers**

- Islet cell hyperplasia and  $\beta$ -cell hypertrophy
- Obesity and macrosomia
- Hypoglycemia with low free fatty acid concentration
- Rapid glucose disappearance rate
- Higher plasma insulin-like activity after glucose administration
- Umbilical vein reactive immunoinulin increase
- Increased C peptide and proinsulin concentrations

Reprinted from Cowett RM. The infant of diabetic mother. *NeoReviews*. 2002;3:e173–e189.

may cause hypoglycemia in IDMs include decreased catecholamine and glucagon secretions as well as diminished hepatic glucose production and decreased oxygenation of fatty acids (Box 98-1).

The pathogenesis of the increase in congenital anomalies among IDMs is probably related to poor glycemic control at conception and during the first trimester of pregnancy. Hyperglycemia in the fetus alters lipid metabolism, generates an excess of reactive oxygen species, and activates apoptosis, all of which can result in fetal malformations. Uteroplacental vascular disease and genetic predisposition may play roles as well. The most common malformations are noted in the heart, central nervous system, and urinary system.

**Delivery**

Mode of delivery is determined by estimated fetal weight on ultrasound, maternal and fetal condition, and obstetric history. Personnel trained in the AAP-AHA Neonatal Resuscitation Program should be available during delivery.

The maternal blood glucose concentration is tightly controlled during labor and delivery. Blood glucose levels higher than 120 to 140 mg/dL (6.66–7.77 mmol/L) are managed with infusion of short-acting insulin.

Continuous fetal monitoring is essential during labor. The American College of Obstetrics and Gynecology recommends elective cesarean section when estimated fetal weight is more than 5 kg in nondiabetic pregnancies, when the estimated weight is more than 4,500 g in diabetic pregnancies, and in cases of arrest of the descent of the fetal head and prolonged second stage of labor in a fetus estimated to be more than 4,500 g. Forceps and vacuum deliveries increase the incidence of shoulder dystocia in macrosomic infants. Patients with advanced microvascular disease are at increased risk of delivery by cesarean.

Infants should be evaluated for presence of any birth injury, congenital malformations, evidence of macrosomia, hypoglycemia, and respiratory distress.

**Evaluation**

IDMs with evidence of perinatal depression, congenital malformations, history of maternal insulin administration, and/or hypoglycemia should be monitored carefully. Infants should be evaluated for hypoglycemia,

hypocalcemia, polycythemia, and hyperbilirubinemia. Careful physical examination should be performed to assess the infant for anomalies. Supportive care should be provided while a continuous evaluation is undertaken.

Infants born to mothers with diabetes may develop asymptomatic neonatal hypoglycemia as early as 1 hour after birth and usually by 12 hours of age. Infants who are LGA may develop low plasma glucose concentrations as early as 3 hours of age.

Asymptomatic IDMs should be fed within the first hour and have a glucose screen 30 minutes after the first feeding. Symptomatic infants who exhibit clinical signs such as jitteriness, cyanosis, seizures, apneic episodes, tachypnea, weak or high-pitched cry, floppiness, lethargy, or poor feeding should have an immediate glucose screen. A glucose level in a symptomatic infant requires intravenous glucose therapy. Clinical laboratory confirmation should immediately check glucose readings less than 47 mg/dL (2.6 mmol/L). Extended monitoring beyond 12 hours of life requires consideration of transfer to a neonatal special or intensive care setting. Hematocrit levels should be checked at 6 to 8 hours and at 24 hours (Figure 98-1). Calcium levels should be checked at 24 hours. Risk assessment for the development of severe hyperbilirubinemia should be performed and include transcutaneous and/or total serum bilirubin testing.

**Physical Examination**

Physical examination should focus on detection of traumatic birth injuries, including a thorough neurologic examination to detect any nerve palsies. Most facial nerve palsies will resolve without intervention, but suspected brachial plexus injuries need thorough evaluation and neurologic follow-up. Cardiac examination should focus on detecting any cardiac murmur, abnormal pulses, and cyanosis. Persistence of symptoms warrants evaluation of the newborn, including electrocardiogram, chest radiograph, 4-limb blood pressures, oxygen saturation, echocardiogram, and consultation with a pediatric cardiologist. Abdominal examination should be performed for detection of any masses and evaluation for any abdominal injuries. An enlarged liver may result from glycogen deposits. Renal masses may be present, especially in the presence of a single umbilical artery.

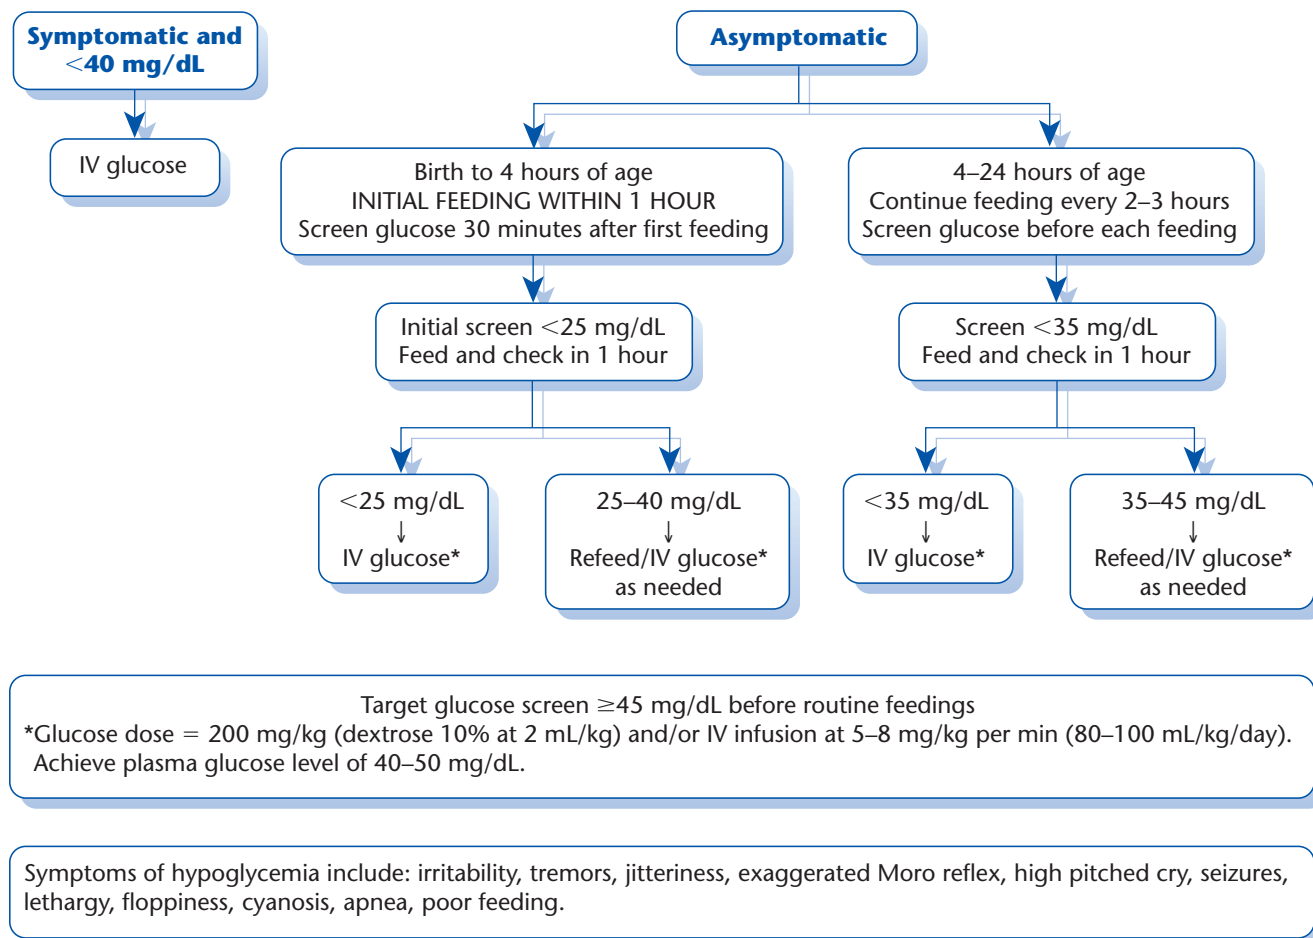

**Frequently Observed Specific Problems**

Rates of adverse neonatal outcomes are 3 to 9 times greater in IDMs compared with infants of nondiabetic mothers. Neonatal complications found in IDMs and LGA infants are listed in Table 98-5.

**Hypoglycemia**

The risk for development of neonatal hypoglycemia increases when there are multiple risk factors such as IDM/LGA, late preterm, and term SGA infants.

The asymptomatic infant should begin breast or formula feeding within the first hour after delivery. The screening and management of postnatal glucose homeostasis is outlined in Figure 98-1.

**Figure 98-1** Glucose monitoring and management in growth-restricted infants, infants of diabetic mothers, and large-for-gestational-age infants. (From Adamkin DH, Committee on Fetus and Newborn. Clinical report—postnatal glucose homeostasis in late preterm and term infants. *Pediatrics*. 2011;127:575–579.)

### Hypocalcemia

IDMs whose mothers had poor glycemic control in the first trimester had decreased bone mineral content at birth secondary to decreased transplacental transfer. Parathyroid function has been shown to be suppressed as well in these infants. Noguchi and colleagues showed hypomagnesemia in 33% of IDMs and speculated low parathyroid function may be related to low magnesium. Excessive jitteriness, alteration in muscle tone, and seizures should warrant investigations for hypoglycemia or hypocalcemia; if these symptoms are present, then ionized calcium levels should be checked. Symptomatic hypocalcemia should be treated with calcium gluconate. If symptoms are mild, then enteral supplementation may be provided. If the hypocalcemia is severe or protracted, the presence of hypomagnesemia should then be ruled out.

### Macrosomia

Hyperinsulinemia in utero affects diverse organ systems, including the placenta. Insulin acts as the primary anabolic hormone of fetal growth and development, resulting in visceromegaly, especially of

the heart and liver, and macrosomia. Fetal macrosomia is reflected by increased body fat, muscle mass, and organomegaly, but not by increased brain or kidney size. Evaluation of nonfasting glucose rather than the fasting glucose in the third trimester of pregnancy is an important measure in preventing macrosomia.

### Traumatic Birth Injuries

As a result of their large size, LGA newborns experience complications of birth trauma, which include shoulder dystocia, and they are also at greater risk for perinatal depression. LGA neonates are more likely to be delivered by cesarean. Injury to the brachial plexus, sometimes associated with phrenic nerve injury, may occur as a result of macrosomia and shoulder dystocia. Injury to abdominal organs may lead to hepatic and adrenal hemorrhage. Injury to external genitalia has occasionally been seen.

### Asphyxia

Although the specific cause of perinatal asphyxia is unclear, it may be caused by difficulty in the

Table 98-5

### Presence of Complications in Large-for-Gestational-Age Infants and Infants of Diabetic Mothers

COMPLICATION	LARGE FOR GESTATIONAL AGE	INFANTS OF DIABETIC MOTHERS

Modified from Cowett RM. The infant of diabetic mother. *NeoReviews*. 2002;3:e173–e189; Cowett RM. Neonatal care of the infant of diabetic mother. *NeoReviews*. 2002;3:e190–e196.

intrapartum period resulting from relative macrosomia. Umbilical arterial cord blood pH and base deficit and cord lactate levels can provide early biochemical assessment of the fetus's physiologic status. Asphyxia may have diverse consequences. It may acutely affect respiratory, renal, central nervous system, and gastrointestinal functioning. Restriction of fluids may be indicated until the degree of injury to the central nervous system and kidneys has been ascertained.

#### Polycythemia

Polycythemia (venous hematocrit >65% [ $>0.65$  fraction of red blood cells]) may be associated with acrocyanosis, hypoglycemia, irritability, or poor feeding. A higher than normal incidence of neonatal necrotizing enterocolitis is seen in IDMs with polycythemia and concurrent hypoglycemia; therefore, they should be fed cautiously. Hyperviscosity resulting from polycythemia may cause renal vein thrombosis, stroke, and other organ damage.

The mechanisms responsible for increased fetal erythropoiesis are not clear, but erythropoietin does not seem to be responsible for polycythemia in IDMs. Late erythroid progenitor colonies are particularly sensitive to insulin, leading to polycythemia and an increase of nucleated red blood cells in IDMs.

#### Jaundice

Hyperbilirubinemia is observed more often in IDMs than in healthy neonates, possibly because of increased bruising secondary to macrosomia and

polycythemia. Management of neonatal hyperbilirubinemia in IDMs and LGA newborns is done according to the guidelines for managing jaundice in other term newborns (see Chapter 99, Neonatal Jaundice).

#### Respiratory Distress

IDMs born only slightly preterm (36 to 37 weeks' gestation) may have respiratory distress syndrome as a result of delayed maturation of surfactant, especially in mothers with class A, B, and C diabetes. Fetal hyperinsulinism may adversely affect the lung maturation process in IDMs by antagonizing the action of cortisol, restricting substrate availability for surfactant biosynthesis, and impeding fibroblast-pneumocyte factor, which stimulates type II alveolar cells to produce surfactant.

IDM neonates may also exhibit respiratory distress resulting from transient tachypnea of the newborn, meconium aspiration, air-leak syndromes, or diaphragmatic paralysis.

#### Poor Feeding

Poor feeding is a major problem in IDMs; it occurs in almost one-third of infants and is often present in the absence of other problems. Poor feeding may occasionally be related to prematurity, respiratory distress, or other problems and is a major cause of prolonged hospital stay and parent-infant separation. Some IDMs have been reported to have increased concentrations of amylin peptide, an inhibitor of gastric motility that is co-secreted with insulin, which may explain the poor feeding in these neonates.

### **Congenital Anomalies**

IDMs are at 3 times the risk for malformations compared with infants of nondiabetic mothers. Poor metabolic control in the first trimester is correlated with major anomalies in IDMs. The recognized complications in IDMs include sacral agenesis, femoral hypoplasia, heart defects, and cleft palate. Others include preaxial radial defects, microtia, cleft lip, microphthalmos, holoprosencephaly, microcephaly, anencephaly, spina bifida, hemivertebrae, urinary tract anomalies, and hallucal polydactyly. Strategies to reduce the risk for congenital anomalies have focused on normalizing the intrauterine metabolic environment before conception, especially in women who have diabetes.

### **Congenital Heart Disease and Cardiomyopathy**

The strongest associations with maternal type 1 diabetes have been noted for double-outlet right ventricle and truncus arteriosus. No such associations have been noted with gestational diabetes. IDMs are at increased risk for congestive or hypertrophic cardiomyopathy. Hypertrophic cardiomyopathy in the neonate results from a fetal hyperinsulinemic state. Most of the infants are asymptomatic, and the diagnosis is made by echocardiography. In a small fraction of neonates, outflow tract obstruction may cause left ventricular failure. Propranolol seems to be the therapeutic drug of choice. Resolution of symptoms occurs within 2 to 4 weeks, and resolution of the hypertrophy occurs within 2 to 12 months, with no permanent effect on the myocardium.

### **Renal Vein Thrombosis**

The pathogenesis of renal vein thrombosis remains obscure, although most speculation has centered on the possible role of polycythemia. Sludging of red blood cells, combined with a further reduction in cardiac output as a result of diabetic cardiomyopathy, may be a contributing factor.

### **Small Left Colon**

Neonatal small left colon syndrome is a transient and unique anomaly affecting about 5% of IDMs. Hypoplastic left colon should be ruled out in case of feeding intolerance and inability to pass meconium. The cause of this anomaly is not clear, although hormone imbalance affecting the autonomic nervous system has been proposed as a mechanism. Increased concentrations of amylin peptide may be contributory. The condition usually resolves spontaneously with conservative medical management within the neonatal period.

### **Perinatal Survival**

Despite the problems associated with pregnancy, a mother with diabetes has a 95% chance of having a healthy baby if she participates in a pregnancy management and surveillance program at an appropriate perinatal center.

### **Follow-up**

Postnursery pediatric follow-up care should be based on the specific complications noted during the

neonatal period. Pediatric cardiology follow-up is required for infants with hypertrophic cardiomyopathy or congenital heart disease. Newborns with repeated episodes of hypoglycemia or with any neurologic signs or symptoms should have close neurodevelopmental follow-up and referral to the local early intervention Child Find registry for at-risk infants. Physical therapy and referral to early intervention may be required for newborns with nerve palsies. Urologic consultation may be required for those with renal abnormalities. Long-term follow-up, with particular attention to neurodevelopment and nutrition to lessen the risk for late metabolic problems, is recommended.

### **Long-term Outcome**

#### **Neurodevelopment**

Achieving optimal metabolic control during pregnancy reduces but may not absolutely prevent the risk for poor neurodevelopmental outcome in offspring. Even with improved maternal care, higher maternal fasting  $\beta$ -hydroxybutyrate concentrations in the second and third trimesters are associated with some limitations in intelligence and psychomotor development independent of perinatal complications in offspring. Adverse outcomes are likely with prolonged and severe hypoglycemia. Psychological evaluations show that IDMs are more vulnerable to intellectual impairment, especially if the neonate was born SGA or if the pregnancy was complicated by acetonuria. Children who have a history of growth delay in early diabetic pregnancy should be screened at 4 to 5 years of age for possible developmental impairment using a norm-referenced screening tool, such as the Denver Developmental Screening Test.

#### **Obesity**

Some evidence suggests that the risks for obesity, impaired glucose tolerance, blunted insulin secretion, and hypertension developing during late childhood or adolescence and persisting into adult life are increased in offspring of diabetic mothers.

#### **Insulin-Dependent Diabetes Mellitus**

The risk for developing insulin-dependent diabetes mellitus (IDDM) by 20 years of age in infants born to pregestational diabetic mothers is  $2.1\% \pm 0.5\%$ . The risk for diabetes in offspring of mothers with diabetes is increased in young mothers and is independent of the risk factors for perinatal mortality. The incidence of IDDM is found to be slightly increased in infants born to fathers with IDDM. The mechanism by which alterations in maternal glucose metabolism alter fetal  $\beta$ -cell function is unknown. Infants born to women with gestational diabetes are at increased risk for metabolic syndrome, obesity, and type 2 diabetes in childhood and adolescence.

#### **Cerebral Palsy, Epilepsy, and Intellectual Disability**

The incidence of cerebral palsy and epilepsy is 3 to 5 times higher in IDMs compared with infants of nondiabetic mothers.

### Key Points

- IDMs with evidence of perinatal depression, congenital malformations, history of maternal insulin administration, and hypoglycemia should be monitored carefully.
- Neonatal hypoglycemia (transiently low blood glucose levels) is common in the immediate neonatal period and may be considered a normal feature of adaptation to extrauterine life. No evidence has been found that this condition causes brain injury in the absence of concurrent clinical manifestations.
- Persistent and severe hypoglycemia may be associated with underlying diseases that themselves predispose newborns to brain injury.
- Careful documentation of the clinical and biochemical state, response to treatment, and the pattern of any cerebral injury in neonates with hypoglycemia should be undertaken.
- Poor metabolic control in the first trimester is correlated with major anomalies in IDMs.
- Some evidence exists of increased incidence of obesity and subsequent IDDM in IDMs, particularly children and adolescents born to women with gestational diabetes.
- Long-term follow-up, with particular attention to neurodevelopment and nutrition to lessen the risk for late metabolic problems, is also important.

## Chapter 99

# NEONATAL JAUNDICE

Vishal Subodhbhai Kapadia, MD; Luc P. Brion, MD

### DEFINITION

The term *jaundice*, derived from the French *jaune* for yellow, is defined as yellow pigmentation of sclera, skin, and urine caused by hyperbilirubinemia. Hyperbilirubinemia in the term or late preterm infant greater than 35 weeks' gestation is classified as either physiologic or pathologic based on age-specific statistical analysis of serum bilirubin measurements.

### FREQUENCY

Jaundice occurs in approximately 60% of the 4 million neonates born yearly in the United States. The largest data set on neonatal bilirubin levels in term or near-term infants was obtained by Bhutani and collaborators in 2,840 well newborns (Figure 99-1). This nomogram is reflective of the natural history of neonatal hyperbilirubinemia during the first 48 to 72 hours of life. Thereafter, the low-risk-zone threshold is less accurate because of the sampling bias that resulted in spuriously elevated levels in the lower zones (more than the high-risk-zone 95th percentile in the study). The approximate frequency of high bilirubin levels compiled from several studies is shown in Table 99-1. In a population study in Denmark, hyperbilirubinemia with a serum concentration justifying an exchange transfusion occurred in 25 per 100,000 (1:4,000) term or late preterm infants.

### DIFFERENTIAL DIAGNOSIS

Yellow skin color can develop in children with carotenemia. In contrast with jaundice, carotenemia does

**Figure 99-1** Nomogram for designation of risk in term and late preterm infants. (From Bhutani VK, Johnson L, Sivieri EM. Predictive ability of a predischARGE hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics*. 1999; 103[1]:6–14.)

not affect the color of the sclera and has not been reported in neonates.

EVALUATION

Clinical practice guidelines for managing hyperbilirubinemia in the newborn of 35 weeks’ gestation or more were published by the American Academy of Pediatrics (AAP) in 2004. The key elements and the diagnostic and therapeutic algorithm are shown in Box 99-1 and Figure 99-2, respectively.

Relevant History

Major risk factors for developing severe hyperbilirubinemia are listed in Box 99-2. The best documented prediction of severe hyperbilirubinemia is a total serum bilirubin or transcutaneous bilirubin level that falls within the high-risk zone of the Bhutani curve. A serum or transcutaneous bilirubin level is measured and plotted on the Bhutani curve. This process allows for determination of the degree of risk of the infant to develop significant hyperbilirubinemia. In combination with identified risk factors for neonatal jaundice, the degree of risk can guide the physician’s treatment planning. Relevant history should also include questions

about the potential use by the mother or administration to the neonate of herbs as well as drugs and medications (eg, sulfonamides, many cephalosporins, benzyl alcohol, parabens, methylparaben) that affect bilirubin binding. Box 99-3 lists agents that displace bilirubin from albumin. Family history may reveal 1 or more hereditary disorders of bilirubin production (eg, increased hemolysis), bilirubin metabolism (mutations of the promoter or of the gene coding uridine diphosphate glucuronosyl transferase, causing, respectively, Gilbert and Crigler-Najjar syndromes), or bilirubin excretion (Dubin-Johnson syndrome). The risk for neonatal jaundice is higher when the neonate has Gilbert syndrome and another factor of jaundice, for example, hemolysis or breastfeeding. The risk for severe hyperbilirubinemia is increased in infants of East Asian descent and decreased in black infants. Correct identification of race and ethnicity by asking the mother about the maternal and paternal ancestry is important in assessing the risk to an infant.

The increased risk for severe hyperbilirubinemia in Asian neonates (with 2 parents of Asian origin) may result from hemolysis, frequently caused by glucose-6-phosphate dehydrogenase (G6PD) deficiency, and

Table 99-1 Proposed Definitions for Severity of Hyperbilirubinemia and Its Estimated Occurrence			
TSB LEVEL (mg/dL)	PERCENTILE AFTER 72 HOURS OF AGE	PROPOSED DEFINITIONS	ESTIMATED OCCURRENCE
≥17.0 (291 mcml/L)	>95th	Significant	~1:10
≥20.0 (342 mcml/L)	>99th	Severe	~1:70
≥25.0 (427 mcml/L)	>99.9th	Extreme	~1:700
≥30.0 (513 mcml/L)	>99.99th	Hazardous	~1:10,000

TSB, total serum bilirubin.  
To convert bilirubin concentration from mg/dL into mcml/L, multiply by 17.1.  
Percentiles are approximate. Occurrence is estimated in screened and treated infants based on data reported in Bhutani et al, Stevenson et al, Martinez et al, and Khurana et al. Precise data cannot be compiled because of differences in methodologies, patient selection, and thresholds for intervention.  
From Bhutani VK, Johnson LH, Maisels MJ, et al. Kernicterus: epidemiological strategies for its prevention through systems-based approaches. *J Perinatol.* 2004;24(10):650–662. Reprinted with permission from Macmillan Publishers.

BOX 99-1 Key Elements in Managing Hyperbilirubinemia

1. Promote and support successful breastfeeding.

2. Establish nursery protocols for the identification and evaluation of hyperbilirubinemia.

3. Measure the total serum bilirubin or transcutaneous bilirubin level in newborns jaundiced in the first 24 hours.

4. Recognize that visual estimation of the degree of jaundice can lead to errors, particularly in darkly pigmented infants.

5. Interpret all bilirubin levels according to the newborn’s age in hours.

6. Recognize that newborns at less than 38 weeks’ gestation, particularly those who are breastfed, are

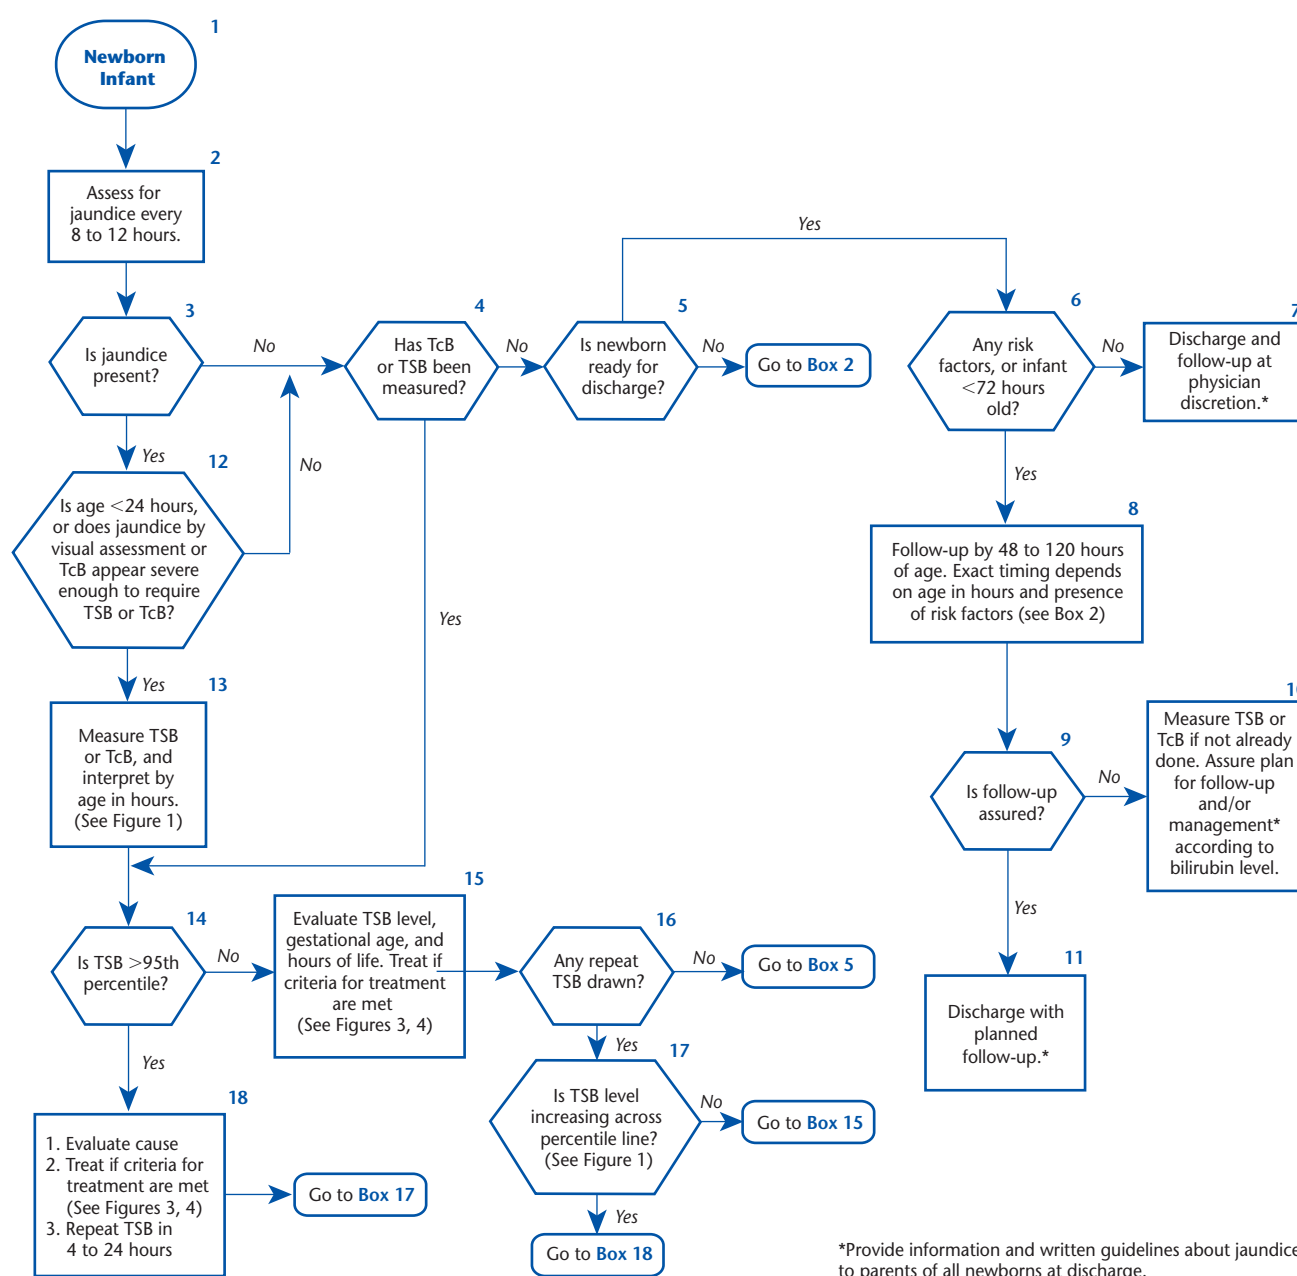

at high risk of developing hyperbilirubinemia and require close surveillance and monitoring.

7. Perform a systematic assessment of all newborns before discharge for the risk for severe hyperbilirubinemia.

8. Provide parents with written and verbal information about newborn jaundice.

9. Provide appropriate follow-up based on the time of discharge and the risk assessment.

10. Treat newborns, when indicated, with phototherapy or exchange transfusion.

**Figure 99-2** Diagnostic and therapeutic algorithm for jaundice in the newborn nursery. TcB, transcutaneous bilirubin level; TSB, total serum bilirubin level. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Clinical practice guideline: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics. 2004;114[1]:297–316.)

from abnormal bilirubin metabolism (eg, mutations affecting abundance or function of uridine diphosphate glucuronosyl transferase, thereby limiting glucuroconjugation). Neonates who carry the nucleotide 211 GA or AA variation within coding region in the *UGT1A1* gene are more susceptible to developing early-onset neonatal breastfeeding jaundice. In addition, increased risk for bilirubin toxicity in Asian neonates may result from displacement of bilirubin from albumin caused by exposure to herbals given to the

neonate (eg, Chuen-Lin, [*Coptis chinensis/japonicum*], a popular herb given to 28% to 51% of Chinese neonates) or taken by pregnant or breastfeeding mothers (eg, berberine, the major ingredient of the Chinese herb huanglian [*Coptis chinensis*]).

Sporadic genetic mutations affecting the gene encoding G6PD on the X chromosome occur in all ethnic and racial groups; more than 400 gene mutations have been identified. In the United States, black male infants are most often affected. Although black neonates

**BOX 99-2 Risk Factors for Development of Severe Hyperbilirubinemia in Newborns of 35 Weeks' Gestation or More (in Approximate Order of Importance)**

**MAJOR RISK FACTORS**

- PredischARGE total serum bilirubin or transcutaneous bilirubin level in the high-risk zone (best documented method)
- Jaundice observed in the first 24 hours
- Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (eg, glucose-6-phosphate dehydrogenase deficiency), elevated end-tidal carbon monoxide
- Gestational age of 35 to 36 weeks
- Previous sibling required phototherapy
- Cephalohematoma or significant bruising
- Poor feeding
- Exclusive breastfeeding, particularly if nursing is not going well and weight loss is excessive
- East Asian race (race as defined by mother's description)

**MINOR RISK FACTORS**

- PredischARGE total serum bilirubin or transcutaneous bilirubin level in the high- to intermediate-risk zone
- Gestational age 37 to 38 weeks
- Jaundice observed before discharge
- Previous sibling with jaundice
- Macrosomic infant of a diabetic mother
- Maternal age  $\geq 25$  years
- Male gender

**DECREASED RISK\***

- Total serum bilirubin or transcutaneous bilirubin level in the low-risk zone
- Gestational age 41 weeks or more
- Exclusive bottle feeding
- Black race (race as defined by mother's description)
- Discharge from hospital after 72 hours

\*These factors are associated with decreased risk for significant jaundice, listed in order of decreasing importance. From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Clinical practice guideline: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114(1):297–316.

| • Ethacrynic acid   | • Maternal intrapartum medication administration—oxytocin, diazepam, promethazine |

have a low risk for severe hyperbilirubinemia, a subgroup of G6PD-deficient black neonates (12.8%) has a 3-fold increase in risk for hemolysis and jaundice compared with controls.

**Physical Examination**

Jaundice may be diagnosed at a bilirubin level of 5 mg/dL. Interobserver agreement about the presence of jaundice in neonates is only moderate (pairwise  $\kappa$ , 0.48), except for infants with bilirubin levels greater than 12 mg/dL, which is the threshold at which all infants are correctly identified as jaundiced by all examiners. Other important parts of the physical examination include vital signs, size for gestational age, either pallor or plethora, petechiae, bruising, subcutaneous edema, blueberry muffin lesions, vasoconstriction, scalp swelling, cataract, goiter, abdominal mass, hepatosplenomegaly, activity, tone, and neurologic examination. Patients with extreme hyperbilirubinemia are at risk for bilirubin encephalopathy. Acute bilirubin

encephalopathy occurs when bilirubin levels become neurotoxic in infants. Three phases of acute bilirubin encephalopathy have been described. The early acute phase is characterized by lethargy, hypotonia, and poor suck; the intermediate phase by hypertonia alternating with hypotonia (including opisthotonus and retrocollis), high-pitched cry, fever, moderate stupor, and irritability; and the advanced phase by seizures, coma, apnea, pronounced retrocollis, and opisthotonus, with death occurring in severe cases. Although the acute neurologic abnormalities of hyperbilirubinemic infants can be transient, the intermediate and advanced phases have been strongly linked to long-term neurologic sequelae. The intermediate phase may be reversible with exchange transfusion, whereas the advanced phase is irreversible. Kernicterus (yellow discoloration of the basal ganglia and brainstem nuclei caused by bilirubin deposition), or chronic, irreversible sequela of bilirubin toxicity, is characterized by athetoid cerebral palsy, auditory dysfunction, dental enamel dysplasia,

paralysis of upward gaze, and, less often, intellectual and other disabilities.

### Laboratory Testing

The AAP recommendations for evaluating jaundiced infants are listed in Table 99-2. The World Health Organization recommends neonatal screening for G6PD in populations with a prevalence of 3% to 5% or more in boys. Some neonatal screening programs also include testing for hemoglobinopathy.

The total serum bilirubin level is the most important measurement. The physician should be aware that bilirubin measurements on automatic analyzers used in most clinical laboratories can be erroneous if the specimen is hemolyzed or turbid.

If phototherapy is indicated, or if the bilirubin level crosses percentiles on the Bhutani nomogram and is unexplained by the history and physical examination, then a serum level of direct or conjugated bilirubin should be obtained. Conjugated hyperbilirubinemia is defined by a serum conjugated bilirubin concentration greater than 1.0 mg/dL (17.1  $\mu$ mol/L) if the total bilirubin is less than 5.0 mg/dL (85.5  $\mu$ mol/L) or more than 20% of the total bilirubin if the total bilirubin is greater than 5.0 mg/dL (85.5  $\mu$ mol/L). Neonatal cholestasis is defined as conjugated hyperbilirubinemia that occurs in the newborn period. It is caused by diminished bile flow or excretion (or both) of conjugated bilirubin from the hepatocyte into the duodenum. The incidence of neonatal cholestasis is approximately 1 per 2,500 live births. Jaundice is further discussed in Chapter 170.

A comprehensive program of prevention, including universal predischarge neonatal bilirubin screening, significantly reduces the subsequent development of bilirubin levels that are known to place newborns at risk for bilirubin encephalopathy.

The new methods of transcutaneous bilirubin assessment, valid in many populations regardless of skin

color, have led to a decrease in the number of blood samples required before and after discharge in term or late preterm infants. Importantly, transcutaneous bilirubin assessment and clinical examination of jaundice are unreliable after phototherapy.

Additional tests indicated in newborns with early or severe hyperbilirubinemia (see Table 99-2) include blood type and Coombs test, complete blood count and smear, reticulocyte count, end-tidal carbon monoxide concentration (if available), and G6PD. Testing for G6PD deficiency is warranted when the newborn is of African, Asian, Mediterranean, or Middle Eastern descent. Among babies with G6PD deficiency (male infants with the defective gene and homozygous female infants) the rate of hyperbilirubinemia is twice that for unaffected newborns. G6PD deficiency should be considered in neonates who develop jaundice during the first day of life, have a family history of a sibling with unexplained hyperbilirubinemia, or have a bilirubin level greater than the 95th percentile on the Bhutani nomogram, and in Asian male infants. The smear may show anomalies such as abnormal erythrocyte volume, ovalocytosis, elliptocytosis, spherocytosis (seen in congenital spherocytosis and in ABO disease), Heinz bodies (suggestive of G6PD deficiency), stomatocytosis, pyropoikilocytosis, thrombocytopenia, or an abnormal white cell count suggestive of sepsis. If hemolysis is confirmed, additional tests to consider may include tests for minor group incompatibility, a workup for congenital or acquired infection, and hemoglobin electrophoresis to rule out thalassemia or thalassemia trait (which could cause hemolysis in association with G6PD deficiency). The newborn screening program may include hemoglobin electrophoresis. Additional tests may be considered, such as autoimmune antibodies, vitamin E level, and tests for pyruvate kinase deficiency and other rare deficiencies of the glycolytic, hexose monophosphate, and

**Table 99-2**

### Laboratory Evaluations for the Jaundiced Newborn of 35 Weeks' Gestation or More

INDICATIONS	ASSESSMENTS
Jaundice in first 24 hr	Measure TcB, TSB, or both
Jaundice appears excessive for age	Measure TcB, TSB, or both
Infant receiving phototherapy or TSB rising rapidly (ie, crossing percentiles and unexplained by history and physical examination)	Blood type and Coombs test, if not obtained with cord blood Complete blood count and smear Measure direct or conjugated bilirubin Option: perform reticulocyte count, G6PD, and ETCOc, if available Repeat TSB in 4–24 hr depending on age and TSB level Perform reticulocyte count, G6PD, albumin, ETCOc, if available
TSB concentration approaching exchange levels or not responding to phototherapy	
Elevated direct (or conjugated) bilirubin level	Perform urinalysis and urine culture. Evaluate for sepsis if indicated by history and physical examination
Jaundice present at or beyond age 3 wk, or newborn is sick	Total and direct (or conjugated) bilirubin level; if direct bilirubin elevated, evaluate for causes of cholestasis Check results of newborn thyroid and galactosemia screen and evaluate newborn for signs or symptoms of hypothyroidism

ETCOc, end-tidal carbon monoxide concentration; G6PD, glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin level; TSB, total serum bilirubin level. From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Clinical practice guideline: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114(1):297–316.

erythrocyte metabolic pathways. Measuring serum albumin is indicated if the bilirubin approaches exchange transfusion level. Prolonged jaundice should raise the suspicion of hypothyroidism, galactosemia, and cholestatic jaundice.

## MANAGEMENT

The AAP and The Joint Commission recommend a universal systematic approach to reduce the risk for severe hyperbilirubinemia and kernicterus. The key elements of the AAP recommendations are summarized in Box 99-1.

Postnatal age-, gestational age-, and risk factor-specific criteria for phototherapy are shown in Figure 99-3. Low-intensity phototherapy can be provided at home to newborns for whom phototherapy is optional, whereas high-intensity phototherapy requires hospital care. Phototherapy reduces the risk that bilirubin levels will reach a level at which exchange transfusion is recommended. Approximately 5 to 10 newborns with serum bilirubin levels ranging from 15 to 20 mg/dL (257–342  $\mu\text{mol/L}$ ) will receive phototherapy to prevent bilirubin in 1 newborn from reaching 20 mg/dL (a number at which exchange transfusion may be recommended). The efficacy of

phototherapy is best with special blue or with blue-green lights and increases with increasing spectrum irradiance, spectrum power (irradiance by unit of surface), and total serum bilirubin. The efficacy is reduced in patients with hemolysis and in infants with cholestasis. Side effects of phototherapy include weight loss, gastrointestinal problems, parental anxiety related to the need for protective eye patches, development of bronze baby syndrome in newborns with cholestasis, and, rarely, purpura, possible growth of melanocytic nevi, and bullous eruptions. Phototherapy is contraindicated in infants with congenital erythropoietic porphyria, in whom it causes severe blistering. Given that the recently developed phototherapy devices do not significantly increase insensible water loss, routine increase in fluid administration is not necessary for patients who undergo phototherapy. However, newborns with clinical or laboratory evidence of dehydration should receive additional fluid.

Postnatal age-, gestational age-, and risk factor-specific criteria for exchange transfusion are shown in Figure 99-4. The ratio of bilirubin to albumin can be used together with the total bilirubin level as an additional factor in determining the need for exchange transfusion.

- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors: Isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin  $<3.0$  g/dL (if measured).
- For well infants 35–37 6/7 weeks can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 weeks and at higher TSB levels for those closer to 37 6/7 weeks.
- It is an option to provide conventional phototherapy in the hospital or at home at TSB levels 2–3 mg/dL (30–50  $\mu\text{mol/L}$ ) below those shown, but home phototherapy should not be used in any infant with risk factors.

**Note:** These guidelines are based on limited evidence, and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy, which should be used when the TSB exceeds the line indicated for each category. Infants are designated as at high risk because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin.

Intensive phototherapy implies irradiance in the blue-green spectrum (wavelengths of approximately 430–490 nm) of at least 30  $\text{mcgW/cm}^2$  per nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's surface area as possible. Note that irradiance measured below the center of the light source is significantly greater than that measured at the periphery. Measurements should be made with a radiometer specified by the manufacturer of the phototherapy system.

If total serum bilirubin levels approach or exceed the exchange transfusion line, the sides of the bassinet, incubator, or warmer should be lined with aluminum foil or white material, which will increase the surface area of the newborn exposed and will increase the efficacy of phototherapy. If the total serum bilirubin does not decrease or if it continues to rise in a newborn who is receiving intensive phototherapy, then these results strongly suggest the presence of hemolysis. Newborns who receive phototherapy and have an elevated direct-reacting or conjugated bilirubin level (cholestatic jaundice) may develop the bronze-baby syndrome.

**Figure 99-3** Guidelines for phototherapy in infants of 35 or more weeks' gestation. *B/A*, Bilirubin/albumin; *TcB*, transcutaneous bilirubin level; *TSB*, total serum bilirubin level; *G6PD*, glucose-6-phosphate dehydrogenase. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Clinical practice guideline: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics. 2004;114[1]:297–316.)

- The dashed lines for the first 24 hours indicate uncertainty as a result of a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if newborn shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if TSB is  $\geq 5$  mg/dL (85 mcgmo/L) above these lines.
- Risk factors: Isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin, and calculate B/A ratio.
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If newborn is well and 35–37 6/7 weeks (median risk) can individualize TSB levels for exchange based on actual gestational age.

**Note:** These suggested levels represent a consensus of most of the committee but are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if the TSB rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, then repeat TSB measurement every 2 to 3 hours, and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours.

If the TSG is at or approaching the exchange level, then send blood for immediate type and crossmatch. Blood for exchange transfusion is modified whole blood (red cells and plasma) crossmatched against the mother and compatible with the infant.

**Intensive phototherapy** implies irradiance in the blue-green spectrum (wavelengths of approximately 430–490 nm) of at least 30 mcgW/cm<sup>2</sup> per nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's surface area as possible. Note that irradiance measured below the center of the light source is significantly greater than that measured at the periphery. Measurements should be made with a radiometer specified by the manufacturer of the phototherapy system.

If total serum bilirubin levels approach or exceed the exchange transfusion line, the sides of the bassinet, incubator, or warmer should be lined with aluminum foil or white material, which will increase the surface area of the newborn exposed and will increase the efficacy of phototherapy. If the total serum bilirubin does not decrease or if it continues to rise in a newborn who is receiving intensive phototherapy, then these results strongly suggest the presence of hemolysis. Newborns who receive phototherapy and have an elevated direct-reacting or conjugated bilirubin level (cholestatic jaundice) may develop the bronze-baby syndrome.

The following B/A ratios can be used together with but not in lieu of the TSB level as an additional factor in determining the need for exchange transfusion:

Risk Category	B/A Ratio at Which Exchange Transfusion Should Be Considered	
	TSB mg/dL/Alb, g/dL	TSB mcgmo/L/Alb, mcgmo/L
Newborns $\geq 38$ 1/7 wks	8.0	0.94
Newborns 35 0/7–36 6/7 weeks and well or $\geq 38$ 0/7 wks if higher risk or isoimmune hemolytic disease of G6PD deficiency	7.2	0.84
Newborns 35 0/7 wks if higher risk or isoimmune hemolytic disease or G6PD deficiency	6.8	0.80

**Figure 99-4** Guidelines for exchange transfusion in infants of 35 or more weeks' gestation. B/A, Bilirubin/albumin; TcB, transcutaneous bilirubin level; TSB, total serum bilirubin level; G6PD, glucose-6-phosphate dehydrogenase. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Clinical practice guideline: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics. 2004;114[1]:297–316.)

Double-volume exchange transfusion has a low but significant risk for complications and should be performed only by trained personnel in a neonatal intensive care unit with full monitoring and resuscitation capabilities.

Based on Gottstein's systematic review (which included 4 small trials) the Subcommittee on Hyperbilirubinemia concluded in 2004: "Intravenous gamma globulin administration is effective in reducing the need for exchange transfusion in infants with isoimmune hemolysis caused by Rh or ABO incompatibility. It is indicated for neonates with isoimmune hemolysis if the serum bilirubin level is rising despite intensive phototherapy or if the bilirubin level is within 2 to

3 mg/dL of the level of bilirubin at which the determination is made that an exchange transfusion becomes necessary to prevent the risk of developing kernicterus." The evidence for the use of intravenous immunoglobulin for isoimmune hemolysis in the neonate will need to be reviewed to take new trials into account.

Jaundice is a frequent reason for readmission of neonates during the first 2 weeks after newborn nursery discharge. Criteria to refer and to admit are listed at the end of this chapter, and guidance for the timing of follow-up care is provided in Table 99-3. The rate of readmission for healthy infants for the treatment

Table 99-3 Follow-up of Newborn With Hyperbilirubinemia	
NEWBORN DISCHARGED	TIMING OF FOLLOW-UP VISIT
Before age 24 hr Between 24 and 47.9 hr Between 49 and 72 hr Before 48 hr <sup>a</sup>  Few or no risk factors <sup>a</sup> Elevated risk factors Elevated risk factors AND appropriate follow-up cannot be ensured	By 72 hr By 96 hr By 120 hr Two follow-up visits may be required: The first at 24–72 hr The second at 72–120 hr Can be seen after longer intervals Earlier or more frequent follow-up Delay discharge either until appropriate follow-up can be ensured or the period of greatest risk has passed (72–96 hr)

<sup>a</sup>Clinical judgment should be used in determining follow-up.

**BOX 99-4 Example of a Clinical Pathway for Management of the Newborn Readmitted for Phototherapy or Exchange Transfusion**

**TREATMENT**

- Use intensive phototherapy or exchange transfusion (or both) as indicated in Figure 99-3 and Figure 99-4.

**LABORATORY TESTS**

- TSB and direct bilirubin levels
- Blood type (ABO, Rh)
- Direct antibody test (Coombs test)
- Serum albumin
- Complete blood cell count with differential and smear for red cell morphology
- Reticulocyte count
- End-tidal carbon monoxide (if available)
- G6PD if suggested by ethnic or geographic origin or if poor response to phototherapy
- Urine for reducing substances
- If history, presentation, or both suggest sepsis, perform blood culture, urine culture, and cerebrospinal fluid for protein, glucose, cell count, and culture.

**INTERVENTIONS**

- If TSB ≥25 mg/dL (428 mcmol/L) or ≥20 mg/dL (342 mcmol/L) in a sick newborn or newborn
- In newborns with isoimmune hemolytic disease and TSB level rising despite intensive phototherapy or within 2 to 3 mg/dL (34–51 mcmol/L) of exchange

level, administer intravenous immunoglobulin 0.5 to 1 g/kg over 2 hours and repeat in 12 hours if necessary.

- If newborn's weight loss from birth is >12% or clinical or biochemical evidence of dehydration exists, then recommend formula or expressed breast milk. If oral intake is in question, then give intravenous fluids.

**FOR NEWBORNS RECEIVING INTENSIVE PHOTOTHERAPY**

- Breastfeed or bottle feed (formula or expressed milk) every 2 to 3 hours.
- If TSB ≥25 mg/dL (428 mcmol/L), repeat TSB within 2 to 3 hours.
- If TSB 20 to 25 mg/dL (342–428 mcmol/L), repeat within 3 to 4 hours.
- If TSB <20 mg/dL (342 mcmol/L), then repeat in 4 to 6 hours. If TSB continues to fall, then repeat in 8 to 12 hours.
- If TSB is not decreasing or is moving closer to level for exchange transfusion or the TSB/albumin ratio exceeds levels shown in Figure 99-4, then consider exchange transfusion (see Figure 99-4 for exchange transfusion recommendations).
- When TSB is <13 to 14 mg/dL (239 mcmol/L), discontinue phototherapy.
- Depending on the cause of the hyperbilirubinemia, measuring TSB 24 hours after discharge to check for rebound is an option.

G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin level. From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Clinical practice guideline: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114(1):297–316.

of jaundice in California in 1991 to 1998 ranged between 10% and 15% for full-term infants and between 24% and 32% for late preterm infants. The clinical pathway for management of the newborn readmitted for phototherapy or exchange transfusion is shown in Box 99-4. The AAP recommends not delaying discharge from the hospital to observe the newborn for rebound

bilirubin level. Instead, a follow-up bilirubin measurement within 24 hours after discharge is recommended if phototherapy is used for hemolytic disease or initiated early and discontinued before 3 to 4 days of age. A recent study suggested a significant association with a higher rebound bilirubin level among newborns with a positive direct Coombs test, for

newborns with a gestational age younger than 37 weeks, and in instances in which phototherapy is initiated before 72 hours of life.

## PREVENTION

Because breastfeeding is the second independent risk factor for the development of hyperbilirubinemia, optimizing breastfeeding is an essential component in the prevention and management of neonatal hyperbilirubinemia. One major aspect of prevention is early initiation and frequent breastfeeding, at least 8 to 12 times per day for the first several days. Two types of hyperbilirubinemia may be observed in breastfed infants: (1) breastfeeding jaundice (also called *breast-non-feeding jaundice*) and (2) breast milk jaundice. (See Chapter 88, Breastfeeding the Newborn.) Breastfed infants who develop jaundice should be continued on frequent breastfeeding. Supplementation with expressed milk or formula is indicated only if the intake seems inadequate despite intervention, if weight loss is excessive, if the newborn appears dehydrated, or for breast milk jaundice when levels reach greater than 20 to 25 mg/dL in an otherwise healthy infant and when a diagnostic interruption of breastfeeding may be helpful.

The US Food and Drug Administration (FDA) has approved no medication for preventing hyperbilirubinemia. A small randomized trial has shown that hyperbilirubinemia in breastfed infants can be reduced by inhibiting  $\beta$ -glucuronidase, thereby reducing the enterohepatic cycle of bilirubin. Glycerin suppositories during the first 48 hours do not significantly affect the level of bilirubin at 38 hours of life. Several studies have shown that in patients with hemolytic anemia, the early postnatal administration of a single dose of tin mesoporphyrin, an inhibitor of heme oxygenase, is highly effective in reducing the risk for hyperbilirubinemia. However, this inhibitor is nonspecific, thereby potentially inhibiting heme oxygenase in the brain. Long-term follow-up data are required before this drug receives FDA approval for this indication.

## LONG-TERM OUTCOME, NEURODEVELOPMENTAL FOLLOW-UP, AND MEDICAL-LEGAL RISKS

The clear guidelines of the AAP and The Joint Commission for prevention, intervention, and follow-up for hyperbilirubinemia in the term or late preterm neonate based on risk factors and total serum bilirubin levels help the physician minimize the medical-legal risk for kernicterus. However, the US Preventive Task Force found only limited evidence supporting efficacy of screening and therapy to prevent chronic bilirubin encephalopathy.

Any term or late preterm neonate who develops acute or chronic bilirubin encephalopathy or presents with a peak bilirubin  $>25$  mg/dL should be entered into the pilot Kernicterus Registry, which in 2013 had records of 216 patients. Peak or admission serum bilirubin concentrations in these patients ranged from 20.7 to 59.9 mg/dL. In this registry, 8% of those who died with kernicterus or developed residual neurologic sequelae had a total serum bilirubin level of 20.7 mg/dL to 25.0 mg/dL, and 50% had a value less than 30.1 mg/dL.

The major underlying root cause for kernicterus in this registry is systems failure of services by multiple providers at multiple sites and inability to identify the at-risk infant and manage severe hyperbilirubinemia in a timely manner. Experimental and clinical data strongly suggest that measurement of free bilirubin may improve risk assessment for long-term neurotoxicity. In a neonate exposed to an agent that unbinds bilirubin, using (measured or estimated) unbound bilirubin levels rather than total serum bilirubin levels to assess the need for phototherapy or exchange transfusion seems prudent. Metabolic acidosis increases free bilirubin levels in the blood.

In patients readmitted with serum bilirubin concentration greater than 25 mg/dL (26.4 to 36.9 mg/dL), most with acute signs of encephalopathy, magnetic resonance imaging may show increased T1 signal at the level of the basal ganglia or brainstem nuclei. In one series, neurologic signs normalized in 4 of 5 infants and magnetic resonance imaging results normalized in 2 of 3 infants by 2 years of age.

Healthy neonates with nonhemolytic hyperbilirubinemia and moderately elevated serum bilirubin levels (13.6 to 26.0 mg/dL) may exhibit minor neurologic dysfunction when examined during the first year of life. In one series, a strong dose-response relationship between the degree of hyperbilirubinemia and the severity of minor neurologic dysfunction was present at 12 months of age.

In contrast, in a series of 132 neonates with peak serum bilirubin levels of at least 25 mg/dL (most up to 29.9 mg/dL) and treated with phototherapy or exchange transfusion, neurodevelopment was normal beyond 2 years of age when examined at a median age of 5.8 years.

Severe anomalies of the brainstem-evoked response are observed in patients with serum bilirubin levels greater than 20 mg/dL. Patients with hyperbilirubinemia at a serum level requiring exchange transfusion should be tested for sensorineural hearing loss by brainstem auditory evoked response, regardless of the results of hearing screening using otoacoustic emission, and should have audiologic monitoring every 6 months until the age of 3 years. Long-term neurodevelopmental follow-up appears justified in patients suspected of or confirmed with bilirubin encephalopathy and those with total serum bilirubin greater than 25 mg/dL. The toxic effect of hyperbilirubinemia on auditory brainstem pathways might be transient provided that prompt treatment is initiated. A recent study found no relationship between the abnormalities of the brainstem auditory evoked potentials and neurodevelopmental status. Accumulating evidence suggests an association between exposure to neonatal jaundice and autistic disorders, as well as perhaps other disorders of psychological development. Gestational age, parity, and season of birth seem to play important roles in this association.

## WHEN TO REFER

- Preparation for possible exchange transfusion: total serum bilirubin greater than the level recommended for exchange transfusion or total serum bilirubin greater than 25 mg/dL

(428  $\mu\text{mol/L}$ ) at any time or signs of bilirubin encephalopathy

- Need for intravenous immunoglobulin therapy: isoimmune hemolytic disease with a total serum bilirubin level rising despite intensive phototherapy or within 2 to 3  $\text{mg/dL}$  (34–51  $\mu\text{mol/L}$ ) of exchange transfusion level
- Sick newborn who needs to be evaluated and treated for possible sepsis
- Cholestatic jaundice, defined as a direct or conjugated bilirubin level greater than 1  $\text{mg/dL}$  if total bilirubin is less than 5  $\text{mg/dL}$ , or above 20% of total serum bilirubin if the latter is greater than 5  $\text{mg/dL}$
- Prenatal diagnosis of isoimmune hemolysis
- Newborn with poor response to high-intensity phototherapy
- Suspicion of bilirubin neurotoxicity

### WHEN TO ADMIT

- Emergency admission: total serum bilirubin greater than the level recommended for exchange transfusion or total serum bilirubin greater than 25  $\text{mg/dL}$  (428  $\mu\text{mol/L}$ ) at any time
- Need for intravenous immunoglobulin therapy: isoimmune hemolytic disease with a total serum bilirubin level rising despite intensive phototherapy or within 2 to 3  $\text{mg/dL}$  (34–51  $\mu\text{mol/L}$ ) of exchange transfusion level
- Routine admission or home phototherapy: total serum bilirubin above the level recommended for phototherapy (usually total serum bilirubin >18  $\text{mg/dL}$ )
- Sick infant who needs to be evaluated for and treated for dehydration or possible sepsis
- Suspicion of bilirubin neurotoxicity

## Chapter 100

# RESPIRATORY DISTRESS AND BREATHING DISORDERS IN THE NEWBORN

Suhas M. Nafday, MD, MRCP(Ire), DCH; Christina Long, DO

## INTRODUCTION

### Physiologic Changes at Birth

The transition from intrauterine to extrauterine life requires establishment of effective pulmonary gas exchange. The process of changing from placental to pulmonary gas exchange at birth requires rapid removal of fetal lung liquid from the potential air space. It is a complex process rather than simple mechanical compression of the chest at delivery that results in oral drainage of lung liquid. It is controlled primarily by ion transport across the airway and pulmonary epithelium that entails a supporting role for sodium uptake in alveolar fluid clearance, particularly under stimulated conditions, and the role of glucocorticoids, catecholamines, and oxygen in regulating the activity of this uptake.

During fetal life, pulmonary vascular resistance (PVR), is high and pulmonary blood flow is low; thus, most of the blood from the right side of the heart flows through the ductus arteriosus into the aorta. At birth, clamping the umbilical vessels removes the low-resistance placental circuit and increases systemic

blood pressure, while blood vessels in the lungs relax. As a result, pulmonary blood flow increases immediately by 8- to 10-fold, and the blood flow through the ductus arteriosus decreases. The most important stimuli for increasing pulmonary blood flow are ventilation of the lungs and an increase in oxygen tension.

Significant changes occur during the first 6 hours after birth as part of the process of cardiorespiratory adaptation that lead to a significant increase in oxygenation and a decrease in the arterial pressure of carbon dioxide ( $\text{PaCO}_2$ ). Throughout this period, there are intrapulmonary shunts that persist as the lungs become air filled and the newborn's functional residual capacity (FRC) is established. The initial respiratory pattern is irregular, but respiratory cycles become increasingly rhythmic with modulation of chemoreceptors and stretch receptors. Both term and preterm infants frequently exhibit incomplete or halting expiratory effort during the first minutes of life. Crying is an important part of the transitional process, helping to promote lung expansion and protect lung volume. Breathing patterns in preterm infants are especially vulnerable because of poor respiratory drive, weak muscles, flexible ribs, surfactant deficiency, and impaired lung liquid clearance.

Successful initiation of respiration requires a sufficient pulmonary gas exchange surface area in the lung in conjunction with an adequately developed pulmonary vasculature that supports transport of oxygen and carbon dioxide through the lungs. The lungs must be compliant and able to respond to the metabolic needs of the infant with minimal respiratory effort. The airways, chest wall, respiratory muscles, and neural mechanisms that control respiration must be structurally mature to allow for optimal respiratory function. Three groups of skeletal muscles—the diaphragm, intercostal and accessory muscles, and abdominal muscles—are involved in ventilation. The diaphragm is the primary muscle used during quiet breathing. Respiratory muscle fatigue occurs when the work of breathing increases, when muscle strength is reduced, or when breathing is inefficient. Respiratory fatigue will lead to progressive hypercapnia and apnea. In most instances, this complex series of events goes quite smoothly. However, some babies develop respiratory distress, necessitating evaluation and possible neonatal intensive care.

During the first 2 months after a full-term birth, significant increases occur in lung size, surface area, and lung volume. Changes in the control of breathing and maturation of neural control mechanisms coincide with this rapid phase of lung growth. Development of the respiratory system continues after birth and into childhood. Alveolar remodeling continues until a child is 6 to 7 years of age, with continued alveolar growth into adolescence.

### Normal Physical Findings

Normal physical findings in a newborn include a respiratory rate of 40 to 60 breaths per minute. During active or rapid eye movement (REM) sleep, infants often exhibit irregular respirations with respiratory pauses of 5 seconds or less. In contrast, during non-REM or quiet sleep, a newborn's respiratory rate is

5 to 10 breaths per minute slower than in the awake or REM sleep states. Infants attempt to minimize their work of breathing by adjusting their respiratory rate. In full-term neonates, respiratory rates average around 45 breaths per minute when awake and 35 breaths per minute during sleep, with wide rates of respiration variation. Respiratory rates are typically higher in preterm infants.

### Respiratory Distress Defined

*Respiratory distress* can be defined as tachypnea with respiratory rate greater than 60 breaths per minute, nasal flaring, chest retractions (intercostal, subcostal, and substernal), and expiratory grunting. Respiratory distress may be present with or without cyanosis. Peripheral or acrocyanosis is common in the neonatal period. Central cyanosis, signifying greater than 3 to 5 g/dL of desaturated hemoglobin, is often visible by looking at the newborn's mucous membranes and tongue and, depending on the skin pigmentation, the lips and trunk. Evaluating nail beds is not helpful in neonates; pigmentation of the vermilion border of the lip and facial bruising may also masquerade as cyanosis. Polycythemic infants may appear cyanosed at higher oxygen saturation levels, whereas infants who are severely anemic will appear pale and may not look cyanotic when they are hypoxic. Decreased oxygen saturation, apnea, or both may also be present. Irregular (*seesaw*) or slow respiratory rates of less than 30 breaths per minute, particularly if associated with gasping, are a worrisome sign.

The cause of respiratory distress can be either pulmonary or nonpulmonary in origin. Nonpulmonary causes of respiratory distress include airway, cardiac, or central nervous system (CNS) abnormalities, sepsis, infection, and hematologic, metabolic, or other conditions. Respiratory depression as the result of maternal medications or illicit substance use may also be a contributing factor. The gestational age of the newborn at birth is another factor that influences the risk for respiratory distress after birth. Late preterm neonates between 34 and 37 weeks' gestation, in comparison with full-term infants, experience increased respiratory difficulties. These newborns exhibit higher rates of low Apgar scores, transient tachypnea of the newborn (TTN), respiratory distress syndrome (RDS), persistent pulmonary hypertension, and respiratory failure. Respiratory distress is associated with cesarean delivery, particularly in the absence of labor. Delivery by elective cesarean is associated with higher rates of respiratory morbidity, necessitating neonatal intensive care, oxygen therapy, and cardiorespiratory support (eg, continuous positive airway pressure [CPAP], mechanical ventilation, extracorporeal membrane oxygenation [ECMO]) because of prematurity and surfactant deficiency.

### APPROACH TO THE PATIENT WITH RESPIRATORY DISTRESS

Respiratory distress can be difficult to determine immediately after birth. Many newborns may initially be cyanotic or tachypneic. These symptoms usually

resolve spontaneously in the first 10 to 15 minutes after birth. A thorough history and physical examination are important to distinguish cardiac and noncardiac causes of cyanosis and respiratory distress. The prenatal and perinatal histories, including maternal medication and substance use, are important in the evaluation for respiratory distress. Labor course and evidence of fetal distress provide important information regarding risk factors for a prolonged or difficult transition after birth. Complications occurring during delivery related to meconium passage, perinatal depression, or birth injury may also lead to transitional difficulties and respiratory distress. Many conditions that produce respiratory distress occur in preterm infants, whereas others may occur in full-term infants. In addition, many congenital anomalies may be suspected prenatally because of the presence of maternal complications that develop. Tracheoesophageal fistula, which may cause respiratory distress, is often associated with polyhydramnios, whereas an underlying condition that causes oligohydramnios may lead to pulmonary hypoplasia. Box 100-1 lists various maternal and obstetric conditions associated with neonatal causes of respiratory distress.

### Physical Examination

After a complete history, the newborn should be examined thoroughly. Urgent evaluation and treatment are needed for the infant who appears ill; is apneic; is choking; exhibits poor, labored, or gasping respirations; or has marked retractions or stridor, poor perfusion, or cyanosis. Bradycardia and hypotension also signify serious illness. The newborn's general appearance may provide useful clues to the cause of the child's symptoms. The physician should observe the neonate's color, activity, level of alertness, cry,

posture, and perfusion and assess for dysmorphism. Upper airways obstruction should be suspected in the infant who develops inspiratory stridor. A barrel-shaped chest suggests an air leak, whereas a scaphoid abdomen should lead the physician to consider that the newborn may have a diaphragmatic hernia. Grunting respirations and retractions signify poor lung compliance and often indicate the presence of parenchymal lung disease.

If cyanosis is present, the newborn should be examined while quiet and in a neutral thermal environment to ascertain whether the cyanosis is central or peripheral (acrocyanosis). Acrocyanosis, blue color of the hands and feet when the rest of the body is pink, is frequently seen in newborns. Acrocyanosis is usually normal and is likely to be seen with exposure to cold and in the presence of polycythemia, but it may also be a presenting sign of serious conditions such as sepsis, hypoglycemia, or hypoplastic left heart syndrome. When the baby's temperature has stabilized, it can be determined whether the cyanosis is central or is acrocyanosis. Central cyanosis of the trunk, mucosal membranes, and tongue can occur at any time after birth and is a manifestation of an underlying problem. Different conditions may affect the appearance of cyanosis, including anemia and hyperbilirubinemia. Causes of cyanosis are listed in Table 100-1.

The oxygen saturation level by pulse oximetry is important to check because clinical signs of hypoxemia or cyanosis may be difficult to detect. Oxygen saturations measured by pulse oximetry typically reflect an arterial pressure of oxygen ( $\text{PaO}_2$ ) between 60 and 90 mm Hg. Although oxygen saturation is less than 90% when the  $\text{PaO}_2$  is below 60 mm Hg in the adult with predominantly adult hemoglobin, in the newborn infant, the hemoglobin-oxygen dissociation curve is shifted to the left. Thus, the saturation in a neonate will be less than 90% when the  $\text{PaO}_2$  is below 40 mm Hg. In the rare condition of methemoglobinemia, the infant appears cyanotic but has a high oxygen saturation level. See Figure 100-1 for typical oxygen dissociation curve.

Accurate monitoring of respiratory rate is important. The physician should look for signs of respiratory distress such as nasal flaring, intercostal or subcostal retractions, and grunting. Grunting, the result of partial closure of the glottis during expiration, may be intermittent or continuous. Suprasternal retractions may be another indication of upper airway obstruction. Capillary refill time greater than 2 seconds may indicate poor perfusion, which may contribute to the respiratory distress.

Further examination of the neonate can reveal whether any obvious malformations are present, such as a barrel-shaped chest with meconium aspiration syndrome or pneumomediastinum and a small, narrow chest in cases of asphyxiating thoracic dystrophy, or a scaphoid abdomen if a congenital diaphragmatic hernia is present. The patient may have inspiratory stridor, which can be associated with vocal cord paralysis or laryngotracheomalacia. The chest must be auscultated to listen to heart and breath sounds. Heart sounds may be loud or diminished

### BOX 100-1 Maternal and Obstetric Conditions Associated With Neonatal Causes of Respiratory Distress

#### MATERNAL CONDITIONS

- Drug abuse: drug withdrawal
- Diabetes mellitus: RDS, hypoglycemia, polycythemia, cardiomyopathy
- Infections: pneumonia, sepsis

#### OBSTETRIC CONDITIONS

- Use of general anesthesia: central depression
- Hydrops fetalis: pleural effusion
- Preterm delivery: RDS
- PROM, maternal fever, chorioamnionitis: pneumonia, sepsis
- Meconium-stained amniotic fluid: meconium aspiration syndrome
- Antepartum hemorrhage: anemia, hypovolemia

PROM, premature/prolonged rupture of membranes; RDS, respiratory distress syndrome.

**Table 100-1** Causes of Cyanosis in the Neonate

	ACROCYNANOSIS	CENTRAL CYANOSIS	DIFFERENTIAL CYANOSIS	REVERSE DIFFERENTIAL CYANOSIS
<i>Appearance</i>	Blue color of the hands and feet when the rest of the body is pink	Blue color of the trunk, mucosal membranes, and tongue	Upper part of the body remains pink, and the lower part is cyanotic	Upper part of the body is cyanotic, whereas the lower part remains pink
<i>Possible Causes</i>	Usually normal Exposure to cold Polycythemia Serious conditions such as sepsis, hypoglycemia, or hypoplastic left heart syndrome	Serious pulmonary parenchymal as well as nonparenchymal abnormality Persistent pulmonary hypertension of newborn Cyanotic congenital heart disease	Right-to-left shunt through the patent ductus arteriosus (PDA)	Transposition of great arteries with pulmonary hypertension and shunt through the PDA TGA with PDA and preductal aortic interruption or coarctation Total anomalous pulmonary venous return above the diaphragm with shunt through the PDA

**Figure 100-1** Oxygen dissociation curve. (Modified from the *Merck Manual of Diagnosis and Therapy*, edited by Robert Porter. Copyright © 2013 by Merck Sharp & Dohme Corp., a subsidiary of Merck & Co, Inc, Whitehouse Station, NJ. Available at: [www.merckmanuals.com/professional/](http://www.merckmanuals.com/professional/). Accessed July 14, 2014.)

(eg, pneumopericardium), or a heart murmur may be present. Cardiac murmur may be absent in a neonate with serious cardiac disease. Breath sounds may be unequal bilaterally, with rales, rhonchi, or wheezing (rare). Breath sounds may be diminished or distant in situations that involve pneumothorax, atelectasis, or pleural effusion. Transillumination of the chest may be a useful tool to rule out pneumothorax. Abdominal distention may be present in cases of ascites or bowel obstructions or those caused by hepatosplenomegaly, which may contribute to respiratory distress. Neurologic status is also important. Hypotonia is often a sign of sepsis, asphyxia, or depression as a result of maternal narcotics. Phrenic nerve injury that occurs during a difficult delivery or as a consequence of thoracic surgery may lead to

paralysis of the diaphragm. The differential diagnosis of respiratory distress is listed in Box 100-2.

## EVALUATION OF A PATIENT WITH RESPIRATORY DISTRESS

### Pulse Oximetry and Blood Gas Studies

Evaluation of a newborn with respiratory distress includes pulse oximetry and blood gas analysis. A pulse oximeter measures the oxygen saturation by comparing the amount of red light absorbed by deoxygenated hemoglobin with the amount of infrared light absorbed by oxygenated hemoglobin. If cyanosis is present, preductal (right hand) and postductal oxygen saturations (probe placed on a lower extremity) should be measured. Preductal and postductal saturation differences may indicate intracardiac shunting as a cause of respiratory distress and cyanosis. Interpreting blood gas values based on normal values for newborns is important. Refer to Table 100-2 for normal blood gas values at different ages. If serial blood gas monitoring is required, then the newborn should be transferred to a special care or neonatal intensive care unit (NICU). While interpreting the blood gas results, attention must be paid to errors caused by air bubbles (high  $\text{PaO}_2$  and low  $\text{PaCO}_2$ ), excessive heparin (metabolic acidosis), dilution of samples by intravenous fluids in samples obtained from intravascular lines, and blood gases obtained by arterial puncture (decreased  $\text{PaCO}_2$  with crying).

If signs of respiratory distress are present, then a hyperoxia test can aid in differentiating between cardiac and noncardiac diseases. The test consists of obtaining a baseline right radial (preductal) arterial blood gas measurement with the baby breathing room air and repeating the measurement while the baby is receiving 100% oxygen. A  $\text{PaO}_2$  measurement greater than 300 mm Hg on 100% oxygen is normal, more than 150 mm Hg suggests pulmonary disease,

**BOX 100-2 Differential Diagnosis of Respiratory Distress in the Newborn****AIRWAY OR LUNG PARENCHYMAL DISORDERS**

**Congenital anomalies:** tracheoesophageal fistula, congenital diaphragmatic hernia, pulmonary sequestration, congenital pulmonary airway malformations, pulmonary hypoplasia, choanal atresia or stenosis, laryngeal web, subglottic stenosis, congenital lobar emphysema, chylothorax, external compression of upper airway (vascular ring, tumors, and cysts), laryngotracheomalacia

**Acquired disorders:** transient tachypnea of the newborn, respiratory distress syndrome, meconium aspiration syndrome, pneumonia, pulmonary edema, pulmonary hemorrhage, pneumatocele, pulmonary lymphangiectasia, air leak syndromes (pneumothorax, pneumomediastinum), pleural effusion including hydrops fetalis, trauma (postextubation laryngeal edema, atelectasis, and subglottic stenosis)

**CARDIAC DISORDERS**

**Cyanotic heart lesions:** transposition of the great arteries, total anomalous pulmonary venous return,

truncus arteriosus, tricuspid atresia, pulmonary atresia, Ebstein anomaly

**Acyanotic heart lesions:** left-to-right shunts (patent ductus arteriosus, ventricular septal defect, and, rarely, atrial septal defect), atrioventricular canal defect, coarctation of aorta, aortic stenosis

**MECHANICAL ANOMALIES**

Rib cage anomalies (eg, Jeune syndrome), abdominal distention

**CENTRAL NERVOUS SYSTEM DISORDERS**

Cerebral edema, asphyxia, infection, vocal cord paralysis, diaphragmatic paralysis, intracranial hemorrhage

**MISCELLANEOUS**

Metabolic acidosis, sepsis, polycythemia, anemia, hypoglycemia, hypermagnesemia

**Table 100-2** Range of Blood Gas Values for Healthy Children

and 50 to 150 mm Hg suggests cardiac disease (or severe pulmonary hypertension). Significant metabolic acidosis requires evaluation for evidence of tissue hypoxia, cold stress, an inborn error of metabolism, sepsis, acute renal failure, or loss of pH buffering ions as a result of diarrhea, parenteral nutrition, or renal insufficiency.

**Other Laboratory Tests**

In addition to evaluating the newborn's blood gas values, laboratory studies such as complete blood count with differential, blood culture, C-reactive protein, calcium and magnesium levels, urine drug screen, and metabolic screening of urine and blood may be useful in finding a cause for respiratory distress.

**Imaging**

Any neonate with respiratory distress should also have a chest radiograph performed. The spectrum of diseases that affect the neonate's chest has significant overlap in their radiographic and clinical appearances; therefore, interpreting the radiologic images with the clinical picture is important. Appropriate shielding is necessary to limit radiation-associated risks. A systematic approach to the evaluation of a chest radiograph should include review of the radiograph to confirm the patient's name and medical record number, laterality side markers, film exposure (quality), rotation, inspiratory effort, and the presence of motion and other artifact. The typical radiograph view obtained is the anterior-posterior (AP) view. A

nasogastric tube should be inserted to confirm esophageal continuity, stomach position, and situs. The utility of obtaining a lateral view chest radiograph has been questioned in the past. Addition of a lateral chest radiograph does not increase the diagnostic efficacy of routine chest films in symptomatic infants. No recent studies investigating the value of the lateral chest radiograph have been conducted. However, each case should be evaluated individually, given that valuable information may be obtained for some infants.

The physician must check the position of any tubes, catheters, and lines. The chest wall (thoracic cavity), bones (clavicles, ribs, scapulae, and vertebrae), airway, and diaphragms should also be assessed. The cardiac and thymic silhouettes often appear to be one, although careful inspection will reveal the borders of each. In a newborn, the thymus is often large, but involution may occur rapidly when an infant is ill. The lung fields should be evaluated for the lung volume and position. The lungs may be hyperinflated, underinflated, opaque, or lucent. Each of these descriptions may suggest an underlying condition that aids in formulating a differential diagnosis. The physician may suspect lung hyperinflation and possibly the presence of a pneumomediastinum in a newborn who exhibits a barrel-shaped chest in the hours after birth, particularly if positive pressure ventilation was required in the delivery room. In sick as well as vigorous neonates, obtaining a completely symmetrical radiograph may be difficult. Radiologic findings may change over the first 24 to 48 hours after birth. Consequently, obtaining additional radiographs may be necessary to evaluate for disease progression or improvement.

Evaluating lung density includes evaluating the lungs for evidence of consolidation or atelectasis/collapse. In instances of lung atelectasis/collapse, tracheal and cardiac deviation to the side of the atelectasis/collapse may be seen. Lucency of the lungs is often the result of air trapping, although it may also signify the presence of air leak into the mediastinum (*sail sign* outlining the right lobe of the thymus), pleural or pericardial spaces, or hemithorax. In cases of massive air leak syndrome, lucencies (dissection of pleural air) may be seen in the neck and peritoneal spaces as well. The heart size, shape, and position and pulmonary circulation should also be assessed. The cardiac silhouette (cardiothoracic ratio) may occupy as much as 65% of the hemithorax during the first days of life. The cardiac apex, aortic notch, and gastric bubble are important orientation features that assist in determining the underlying cause for the newborn's respiratory difficulty. Evaluating the pulmonary circulation is important if congenital heart disease or persistent pulmonary hypertension is suspected. Lucent or dark lung fields suggest diminished pulmonary blood flow caused by anatomic or vascular abnormalities.

The position of the diaphragm is helpful in ascertaining lung volume as well as identifying newborns with diaphragmatic hernias. In the latter instance, the diaphragm will be elevated, and the abdominal contents are visible in the hemithorax. Pulmonary hypoplasia that results from limited thoracic space for lung growth will lead to significant respiratory compromise and distress after birth. A newborn

who sustains damage to the phrenic nerve as a result of birth or surgical injury will exhibit respiratory symptoms and elevation of the diaphragm on the affected side. Elevation of the diaphragm may also be seen in eventration of the diaphragm. A nasogastric or orogastric tube should be placed before obtaining a chest radiograph. The presence of a tracheoesophageal fistula is confirmed by seeing a coiled tube in an upper esophageal pouch. Prenatal diagnosis of congenital lung masses may have included fetal sonography and fetal magnetic resonance imaging (MRI). However, most cases of congenital lung masses will be identified after birth as the newborn exhibits respiratory distress. Sonography, computed tomography (CT), or MRI of the chest is used to help characterize congenital lung lesions and aid in diagnosis. These studies also assist in defining the extent of the lesion and identifying associated anomalies.

### Cardiac Tests

If cardiac disease is suspected, then the physician should obtain an electrocardiogram, 4-limb blood pressures, and preductal and postductal oxygen saturation levels. Echocardiography is the definitive investigation for diagnosing congenital heart disease, if available (see Chapter 101, The Newborn With a Heart Murmur or Cyanosis).

## COMMON CAUSES OF EARLY RESPIRATORY DISTRESS IN THE NEWBORN

### Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTN) is a common, relatively benign, self-limited disease diagnosed shortly after birth (Figure 100-2). It is more common in newborns delivered by cesarean section in the absence of labor. Other risk factors include male sex, perinatal asphyxia, history of umbilical cord prolapse, and maternal complications such as asthma, diabetes, and anesthesia or analgesia during labor. Although TTN occurs in preterm infants, it is most common in infants delivered between 37 and 42 weeks' gestation. Complications may occur, such as air leaks, with or without the provision of positive pressure ventilation. Neonates with mild TTN symptoms who transition quickly may be monitored closely in a regular or observation nursery. Newborns who continue to exhibit respiratory distress after a period of transition should be admitted to the NICU for further evaluation, monitoring, and treatment. The pathophysiologic mechanism of TTN involves delayed clearance of fetal lung fluid by the lymphatics and pulmonary circulation with resultant transient pulmonary edema. At birth, the pulmonary epithelium switches from predominantly facilitated  $\text{Cl}^-$  secretion to predominantly active  $\text{Na}^+$  reabsorption with the increased expression of epithelial  $\text{Na}^+$  channels (ENaC). Diminished activity or immaturity of this process may contribute to the development of TTN. Familial clustering of some TTN cases shows a genetic predisposition in the development of this disorder. Antenatal glucocorticoids induce lung  $\text{Na}^+$  reabsorption by increasing the number and activity of

**Figure 100-2** Chest radiograph of neonate with transient tachypnea of the newborn.

channels, even in hypoxia. Because a large release of fetal adrenaline occurs late in labor, stimulating ENaC to start reabsorbing lung fluids, aerolized  $\beta$ -agonists may be used in the treatment. Genetic predisposition for  $\beta$ -adrenergic hyporesponsiveness may cause TTN in the newborn period and asthma or wheezing in older age groups. The clinical findings associated with TTN and treatment strategies are listed in Box 100-3.

### Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) is primarily a disease of preterm infants, although it may affect term neonates, especially infants of diabetic mothers. RDS complicates approximately 1% of pregnancies. The risk for RDS decreases with increasing gestational age: 60% of babies born at fewer than 28 weeks' gestation, 30% of babies born between 28 and 34 weeks' gestation, and fewer than 5% of babies born after 34 weeks' gestation develop RDS.

Late preterm infants born between 34 and 37 weeks' gestation experience a higher risk for respiratory distress after birth than full-term infants because of TTN and RDS.

Other factors that increase the risk for RDS include male sex, maternal gestational diabetes, perinatal asphyxia, hypothermia, multiple gestations, and a family history of a sibling who developed RDS. The disease is more prevalent among white infants. Hemodynamic instability caused by hypothermia or hypoglycemia may worsen preexisting respiratory difficulties. Antenatal steroids and prolonged rupture of membranes decrease the risk for RDS.

### Pathophysiology

Preterm infants have underdeveloped alveolar sacs and experience a delay in production and secretion of functional surfactant. Such surfactant deficiency leads to noncompliant, stiff lungs resulting in the development of atelectasis (alveolar collapse) at the end of expiration with low FRC and lung injury. Lung injury leads to protein exudation and edema, which can

### BOX 100-3 Findings and Treatment of Transient Tachypnea of the Newborn

#### CLINICAL PRESENTATION

- Tachypnea appears shortly after birth and resolves in 1 to 5 days.
- Nasal flaring, grunting, and retractions occur; crackles or rales are heard on auscultation.
- Hypoxemia occurs.
- Chest radiograph hyperinflation, prominent perihilar vascular markings, and fluid may be present in the fissures. Small pleural effusions may also be present (see Figure 100-2).

#### TREATMENT

- Most infants with transient tachypnea of the newborn do not require treatment.
- Supplemental oxygen: nasal cannula and continuous positive airway pressure providing 5 to 7 cm water may be useful when fractional inspired oxygen requirements exceed 0.4 to 0.5 (40%–50% oxygen). Mechanical ventilation is rarely required.
- Antibiotics may be considered until sepsis has been excluded.
- Provide intravenous hydration and nutrition.
- Avoid fluid overload.
- Diuretics offer little or no benefit.
- Aerosolized  $\beta$ -agonists may have a role in the treatment.

inactivate surfactant further. The acidosis and hypoxia that result from atelectasis and lung injury further interfere with surfactant production. The combination of these events leads to respiratory failure. Ventilation-perfusion mismatch occurs because of the relatively well-perfused but poorly ventilated areas of the lungs that cause hypoxemia and hypercarbia. Hypoxemia promotes pulmonary vasoconstriction that can trigger persistent pulmonary hypertension. In premature infants, respiratory muscle fatigue and a compliant chest wall further impair alveolar ventilation. Surfactant is a mixture of phospholipids and proteins. The most abundant surface-active phospholipid in mature lungs is phosphatidylcholine. In addition to phospholipids, surfactant contains 4 major proteins: surfactant proteins (SPs) A, B, C, and D. Surfactant protein deficiency occurs in a small group of term infants with severe respiratory distress that leads to intractable respiratory failure and death. SP deficiency type B is the most common form of SP deficiency and occurs as an autosomal recessive trait.

### Clinical Presentation

RDS presents at the time of or soon after birth, and symptoms worsen over time. Clinical symptoms of RDS are the same as those of any other respiratory distress: tachypnea, nasal flaring, chest wall retractions, expiratory grunting, and central cyanosis. In the extremely preterm infant, the only clinical symptom of RDS may

**Figure 100-3** 34-weeks' gestation twin born to a 28-year-old primiparous woman with preeclampsia. Baby had progressive respiratory distress requiring nasal continuous positive airway pressure and oxygen.

be apnea. Some infants who have RDS exhibit all of these symptoms, and others may show none.

The typical chest radiograph shows diffuse atelectasis and the classic reticulogranular ground-glass appearance of the lung fields (Figure 100-3). Air bronchograms, which are air-filled bronchi superimposed on the relatively airless parenchyma of the lung tissue, also are seen commonly on chest radiograph. Importantly, the appearance of group B streptococcal pneumonia on chest radiograph can be identical to that of RDS.

### Prevention and Treatment

For prevention, stabilization strategies, and treatment of RDS, see Box 100-4.

### Long-term Prognosis

Survival of patients with respiratory distress is inversely proportional to the gestational age at birth. Long-term morbidities associated with RDS include bronchopulmonary dysplasia, increased risk for pulmonary infection such as respiratory syncytial virus, and increased incidence of retinopathy of prematurity. The introduction of prenatal steroids for acceleration of lung maturity and the development of exogenous surfactant have improved outcomes and decreased mortality in patients with RDS.

### Meconium Aspiration Syndrome

Meconium aspiration syndrome (MAS) is a respiratory disorder that occurs in a newborn who is born through meconium-stained amniotic fluid and whose symptoms cannot otherwise be explained. MAS occurs most frequently in infants who are term, postterm, or small for gestational age. Meconium-stained amniotic fluid occurs in approximately 13% of

live births, with MAS occurring in 5% to 10% of infants born through meconium-stained amniotic fluid with significant neonatal morbidity and mortality. Neonates born through meconium-stained amniotic fluid may have other causes for respiratory distress such as TTN, delayed transition, infection, persistent pulmonary hypertension, air leak, hypovolemia, pulmonary edema, or aspiration of blood. Up to one-third of these infants exhibit perinatal depression at birth. The incidence of MAS has decreased during the past decade in response to improved intrapartum and and postnatal management in developed countries.

Meconium is composed of water and debris from the intestinal tract, including skin, lanugo, bile pigments, lipids from vernix, amniotic fluid and intestinal secretions, glycoproteins, and mucopolysaccharides. Aspiration of meconium occurs during fetal gasping or with the initial breaths after delivery. Although sterile, when meconium is aspirated into the lung, it triggers an inflammatory response through stimulation of cytokine and vasoactive substance production. Respiratory failure and hypoxia develop as a result of poor lung compliance, increased airway resistance, and smaller tidal volumes. Marked ventilation-perfusion abnormality secondary to airways plugged by meconium also occurs. This condition promotes persistent pulmonary hypertension with right-to-left shunting through the ductus arteriosus or the foramen ovale. Aspirated meconium may cause airway obstruction with air trapping, chemical irritation, pneumonia, and inactivate endogenous surfactant. The pathophysiologic mechanisms related to airway obstruction and pulmonary vascular resistance are understood better than issues related to meconium-induced inflammation and subsequent meconium-induced lung injury.

The diagnosis of MAS is confirmed by radiography (Figure 100-4). Streaky, linear, or patchy infiltrates (densities) are present on the initial chest film, and the lungs may appear hyperinflated. Radiologic changes resolve over a 7- to 10-day period, although the chest radiograph may take weeks to normalize in rare instances. A 10% to 30% risk exists for air leak among newborns with MAS. These newborns may often be in the nursery and become acutely tachypneic or cyanotic. Air leak typically occurs within 72 to 96 hours of birth. Box 100-5 summarizes treatment and prevention strategies. Although depressed infants born through meconium-stained fluid are at risk for developing MAS, there is no evidence that endotracheal suctioning of these infants reduces MAS.

### Pneumonia

Pneumonia may be acquired in utero, during delivery, or postnatally. It is classified as early or late. Causes of neonatal pneumonia depend on whether the infection is acquired before, during, or after birth. An extensive range exists of bacterial, parasitic, and viral organisms that are responsible for infection along the pregnancy continuum and are summarized in Box 100-6. Prenatally, the fetus may be exposed to many different pathogens if a maternal infection is present. In addition, a variety of risk factors can be found related to preexisting maternal infection, premature or prolonged membrane rupture, and signs of fetal

**BOX 100-4 Prevention and Treatment Strategies in Respiratory Distress Syndrome****PREVENTION**

- Preterm babies at risk for respiratory distress syndrome (RDS) should be delivered in centers where appropriate skills are available for stabilization and ongoing respiratory support, including NCPAP, intubation and mechanical ventilation.
- Prenatal administration of a single course of prenatal betamethasone to all women at risk for preterm delivery (between 24 and 34 weeks' gestation) including threatened preterm labor, antepartum hemorrhage, preterm rupture of membranes, or any condition requiring elective preterm delivery. There is continuing controversy over the use of repeated courses of prenatal corticosteroids.
- Prevention of prematurity, prevention of asphyxia, avoiding drug depression during preterm labor, avoidance of maternal fluid overload.

**DELIVERY ROOM STABILIZATION**

- Administration of 100% oxygen may be harmful to preterm infants; uncontrolled tidal volumes, either too large or too small, may also be detrimental to the immature lung.
- Delivery room continuous positive airways pressure (CPAP) has come into widespread use, although it is not clear at present if this will reduce the need for subsequent surfactant treatment or mechanical ventilation. Start resuscitation with CPAP of at least 5 to 6 cm H<sub>2</sub>O via mask or nasal prongs to stabilize the airway and establish functional residual volume. Avoid excessive tidal volumes by incorporating resuscitation devices (T-piece resuscitator) that measure or limit the peak inspiratory pressure because this might reduce the risk for lung injury.
- Intubation should be reserved for babies who have not responded to positive pressure ventilation by mask and those requiring surfactant therapy.
- Pulse oximetry in the immediate newborn period provides useful information on heart rate during resuscitation and may help to avoid hypoxemic peaks. During the transitional phase after birth, saturations should rise gradually from about 60% to 90% over 5 minutes. The lowest concentration of oxygen possible should be used during resuscitation, provided there is an adequate heart rate response (>100 beats/minute) because this reduces cerebral vasoconstriction and may reduce mortality.

**TREATMENT**

- Multidisciplinary approach applying basic principles of neonatal care, such as thermoregulation, cardiovascular and nutritional support, treatment of early neonatal infection, and prevention of nosocomial infections.
- Provision of respiratory support: mechanical ventilation or nasal CPAP. Mechanical ventilation is harmful to immature lungs and should be avoided if possible. CPAP of at least 5 cm H<sub>2</sub>O pressure reduces the need for reintubation if applied after extubation from mechanical ventilation. CPAP should be initiated in all babies at risk for RDS, such as those <30 weeks' gestation who are not receiving mechanical

ventilation, until their clinical status can be assessed. Avoiding CPAP levels of  $\geq 8$  cm H<sub>2</sub>O reduces the risk for overdistention and air leak. Heated and humidified high-flow nasal cannula has been incorporated in many neonatal intensive care units because of ease of administration and possibly improved patient tolerance. However, randomized controlled trials are not available to guide therapy. Concerns have been raised, especially in preterm infants weighing <1000 g, regarding lack of measurement of delivered pressure and a potential for increased infection. It may be prudent to use the smallest acceptable nasal cannula in smaller infants to allow for leak around the nares. Adequate infection control surveillance programs should be established.

- Surfactant replacement therapy: meta-analysis of various trials in which natural or synthetic surfactant was used, either as a prophylactic or rescue treatment, shows that surfactant improves oxygenation, decreases air leaks, and reduces infant mortality caused by RDS.
- Prophylaxis (within 15 minutes of birth) may be considered in babies <27 weeks' gestation. Prophylactic surfactant for babies >26 weeks' but <30 weeks' gestation if intubation is required in the delivery suite or if the mother has not received prenatal corticosteroids may be considered.
- Prophylactic surfactant has not been found superior to nasal CPAP and early selective surfactant in decreasing the need for mechanical ventilation in the first 5 days of life and the incidence of main morbidities of prematurity in spontaneously breathing very preterm infants on nasal CPAP.
- Combination of early CPAP with early or prophylactic surfactant administration can lead to further therapeutic improvement (intubation surfactant extubation, or INSURE). When possible, duration of mechanical ventilation should be shortened by immediate (or early) extubation to CPAP after surfactant administration provided the baby is otherwise stable.
- Many institutions practice only rescue surfactant therapy. Initial stabilization with CPAP and rescue surfactant administration, if necessary, is not worse than intubation, mechanical ventilation, and surfactant administration immediately after birth.
- Alternative method of administration of surfactant via an endotracheal catheter while a baby is on CPAP has been reported.
- Natural surfactants should be used in preference to synthetic because they reduce pulmonary air leaks and mortality.
- CPAP can be considered as an alternative to intubation and surfactant therapy.
- In babies receiving oxygen, saturation should be maintained at all times between 90% and 95% because this may reduce retinopathy of prematurity and bronchopulmonary dysplasia and reduce mortality.
- Babies with RDS should routinely have blood cultures preformed before starting treatment with intravenous antibiotics.
- The benefits of inhaled nitric oxide in preterm infants for hypoxemic respiratory failure are being investigated at present.

**Figure 100-4** Term newborn with meconium aspiration syndrome. Arrows highlight meconium infiltrates in the lung.

compromise that, singly or in combination, increase the opportunity for a fetus to develop congenital pneumonia (Box 100-7).

Clinical manifestations of pneumonia are similar to other respiratory disorders in the newborn. Signs of respiratory distress may be seen. Fever or other systemic signs may be present. Systemic findings often mirror manifestations seen with sepsis or other severe infections. A variety of chest radiograph findings may be present in a newborn with pneumonia, such as air bronchograms, diffuse parenchymal infiltrates, lobar consolidation, and pleural effusions. Radiographic findings in group B streptococcal pneumonia may be similar to the reticular granular pattern seen in RDS.

Treatment consists of respiratory support, including oxygen and ventilation if necessary. Broad-spectrum antibiotics must be started expeditiously. If an infecting organism is identified, then antibiotic therapy can be adjusted to the specific organism. Failure to consider the diagnosis in the absence of maternal risk factors for infection and failure to initiate neonatal antibiotics in a timely manner may be a medical-legal pitfall.

Blood counts and blood culture should be obtained. Routine culture of spinal fluid is controversial. Endotracheal culture soon after intubation may be useful. Quantitative measurements of C-reactive protein and other acute-phase reactants have limited positive predictive value. Decisions about antimicrobial treatment should not be based on inflammatory markers alone. Neonates should receive adequate nutritional support and hydration.

*Ventilator-associated pneumonia (VAP)* is a significant cause of nosocomial infection in infants with associated high mortality and morbidity. The exact rate of neonatal VAP is difficult to establish, because

radiographic identification of pneumonia is difficult, especially amongst neonates with significant underlying lung disease such as bronchopulmonary dysplasia (BPD) with high incidence of airway bacterial colonization. Surveillance studies of nosocomial infections amongst NICU patients indicate that the VAP represents 6.8% to 32.3% of nosocomial infections in NICU with significant variability amongst various birth-weight and gestational age categories. Ventilator associated pneumonia has assumed significance because of increasing survival of extremely low-birth-weight neonates in the NICU who require prolonged mechanical ventilation. It is a leading cause of death among hospital-acquired infections and prolongs ventilator time and length of stay.

Stringent clinical criteria to define VAP have been developed by the CDC and the National Hospital Safety Network (NHSN). Criteria include mechanical ventilation within 48 hours of onset of suspected VAP; worsening gas exchange with an increase in oxygen or ventilatory requirements; 2 or more chest radiographs that show new infiltrates, consolidation, cavitation, or pneumatoceles; and at least 3 signs and symptoms. Signs and symptoms may include temperature instability, wheezing, tachypnea, cough, abnormal heart rate, change in secretions, or an abnormal leukocyte count. Current CDC definitions of pneumonia for infants younger than 1 year do not address the uniqueness of mechanically ventilated very low-birth-weight infants who seldom develop fever, wheezing, rhonchi, or cough. Furthermore, radiographic changes and the presence of a respiratory pathogen in blood alone as criteria have low specificity, low sensitivity, and low negative predictive value for the definition of pneumonia.

Recently, many institutions have adopted VAP prevention strategies in the form of a “bundle” approach comprising strict hand hygiene, elevating the head of the bed by 15 to 30 degrees, oral care protocol, suctioning the mouth before endotracheal tube insertion, endotracheal tube suctioning when clinically indicated, and draining ventilator circuits before turning the neonate.

### Chronic Lung Disease of Infancy

Chronic lung disease of infancy (CLDI) represents a heterogeneous group of pulmonary disorders originating in the neonatal period.

Chronic lung disease of infancy is a disorder of intrauterine inflammation and atypical (premature) extrauterine lung development characterized by alveolar simplification. Airway and parenchymal inflammation, a hallmark of CLDI, may also develop following pneumonia/sepsis, meconium aspiration, pulmonary hypoplasia, persistent pulmonary hypertension, apnea, tracheoesophageal fistula, congenital diaphragmatic hernia, congenital heart disease, and congenital neuromuscular disorders. Major contributing factors also include the effects of treatment, including mechanical ventilation, barotrauma, and oxygen toxicity. However, a variety of other issues, such as genetic predisposition, perinatal asphyxia, perinatal infection, and inflammation, may

**BOX 100-5 Management Strategies in the Treatment of Meconium Aspiration Syndrome**

Many newborns with meconium aspiration syndrome (MAS) at birth will transition and have no evidence of respiratory distress. Management of most newborns with MAS is supportive. For newborns with signs of respiratory distress after a meconium delivery, admission to the neonatal intensive care unit is necessary.

**RESPIRATORY SUPPORT**

- Oxygen therapy via oxygen hood: maintain oxygen saturation >95% ( $\text{PaO}_2 = 55\text{--}90$  mm Hg).
- CPAP providing at a level of 5 to 6 cm  $\text{H}_2\text{O}$  may be useful when fractional inspired oxygen requirements exceed 0.4 to 0.5 (40%–50% oxygen).
- Assisted ventilation: pH should be maintained above 7.3,  $\text{PaCO}_2$  in the 40 to 50 mm Hg range, and  $\text{PaO}_2$  targeted at 70 to 80 mm Hg. This may be achieved with a moderate peak inflating pressure preferably not exceeding 25 cm  $\text{H}_2\text{O}$ , a relatively rapid ventilator rate (40–60 breaths/minute), a moderate PEEP (4–6 cm  $\text{H}_2\text{O}$ ), and an adequate expiratory time (0.5–0.7 second) to prevent air trapping. This strategy requires a relatively short inspiratory time of 0.3 to 0.4 second. If the diaphragms on chest radiograph are flat and gas trapping is suspected, the expiratory time should be increased to 0.7 to 0.9 second, PEEP decreased to 3 to 4 cm  $\text{H}_2\text{O}$ , and the rate decreased to allow at least a 0.25-second inspiratory time.
- Close monitoring is important because air trapping may result in hyperinflation and air leak (pneumomediastinum, pneumothorax).
- High-frequency ventilation may be used if the newborn is not responding to conventional ventilation.

- Exogenous surfactant and surfactant lavage
- Sedation
- Inhaled nitric oxide to improve oxygenation, especially in patients with persistent pulmonary hypertension of the newborn
- Experimental therapies: phosphodiesterase (PDE) inhibitors (milrinone, dipyridamole, zaprinast, sildenafil), superoxide dismutase, vasoactive intestinal peptide, adrenomedullin, arginine
- Extracorporeal membrane oxygenation
- Antibiotics
- Maintain fluid and electrolyte balance
- Monitor with serial chest radiographs: watch for air trapping, flat diaphragm, and signs of air leak.

**PREVENTION: ROLE OF SUCTIONING**

Intrapartum suctioning: routine intrapartum oronasopharyngeal suctioning before delivery of shoulder in neonates born through MSAF is not recommended.

Tracheal suctioning: One-third of infants born through MSAF will have meconium in their trachea after delivery even with intrapartum suctioning.

Suctioning is not recommended for the vigorous infant born through MSAF because it does not improve outcomes and may cause complications.

Tracheal suctioning should be performed before positive pressure ventilation in infants born through MSAF who are apneic or nonvigorous (depressed), even if previously vigorous.

CPAP, continuous positive airway pressure; MSAF, Meconium stained amniotic fluid;  $\text{PaO}_2$ , arterial pressure of oxygen; PEEP, positive end-expiratory pressure.

**BOX 100-6 Pathogens Causing Pneumonia in Neonates****PRENATAL**

- Adenovirus
- Rubella
- Herpes
- Mumps
- Cytomegalovirus
- *Toxoplasma gondii*
- *Mycobacterium tuberculosis*
- *Listeria monocytogenes*
- Varicella
- HIV

**INTRAPARTUM**

- Group B *Streptococcus* species

- *Escherichia coli*
- *Klebsiella* species
- Syphilis
- *Neisseria gonorrhoeae*
- *Chlamydia trachomatis*—typically does not occur until after 2 weeks of age

**POSTNATAL**

- Various gram-negative and gram-positive bacteria
- Viruses (respiratory syncytial virus, adenovirus, influenza virus, and others)

**BOX 100-7 Prenatal Risk Factors for Congenital Pneumonia**

- Unexplained preterm labor
- Rupture of membranes before onset of labor
- Membrane rupture more than 18 hours before delivery
- Maternal fever ( $>38^\circ\text{C}$  [ $100.4^\circ\text{F}$ ])
- Uterine tenderness
- Foul-smelling amniotic fluid
- Infection of the maternal genitourinary tract
- Recurrent maternal urinary tract infection
- Gestational history of illness consistent with an organism known to have transplacental pathogenic potential
- Nonreassuring fetal well-being test results
- Fetal tachycardia
- Meconium in the amniotic fluid
- Infant with previous neonatal infection

all contribute to the process. Some full-term infants can develop CLDI following mechanical ventilation used to treat other neonatal respiratory conditions. These pathophysiological changes lead to chronic airflow obstruction, increased work of breathing, and airway hyper-reactivity.

### Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia, first described by Northway in 1967, is a form of CLDI that typically develops in very low-birth-weight infants weighing less than 1,500 g, particularly infants born weighing less than 1,000 g. In 2001, a NIH workshop developed a consensus on a definition of BPD based on gestational age at birth, time of assessment, and severity of disease (see Box 100-8). Bronchopulmonary dysplasia evolves after respiratory distress syndrome (RDS), a disorder of surfactant deficiency in preterm infants treated with oxygen and/or mechanical ventilation ("classic" or "old" BPD). Some extremely preterm infants develop lung disease after an initial period without an oxygen or ventilatory requirement. This condition is also referred to as *chronic lung disease of prematurity*. Advances in neonatal care since the early 1990s have contributed to increased survival of extremely preterm, extremely low-birth-weight infants. Systematic use of antenatal corticosteroids to promote lung maturity and postnatal administration surfactant in very preterm infants with RDS and significant respiratory support requirements has resulted in the identification of a different, "new" form of BPD that is associated with a disruption of lung organogenesis, specifically an arrest of alveolar septation and vascular development in the distal lung and impaired pulmonary function during the first years of life. This form of lung disease, "new BPD," has become the most common cause of CLDI. It is not clear if this new BPD represents a single different disease entity in extremely preterm infants with lung injury, or whether it is a group of entities associated with complex epigenetic, environmental (especially antenatal and postnatal infections), inflammatory-mediated dysregulation of lung maturation, or other factors. Table 100-3 compares the findings in "classic" (old) BPD and the "new" BPD. Figure 100-5 is a radiograph of an infant with classic BPD characterized by diffuse cystic changes, hyperinflation and fibrosis. In contrast, Figure 100-6 illustrates the characteristic finding in the extremely preterm infant who has developed BPD. The changes include minimal airway lesions, pulmonary edema, and arrest of alveolarization.

Thus CLDI contributes to childhood, adolescent, and adult chronic lung disease. Neonatologists, pediatricians, and pediatric pulmonary and cardiology specialists are faced with caring for infants with residual complex lung conditions. Improved ventilation management techniques and the use of surfactant, caffeine, and antenatal steroids have improved outcomes for preterm infants greater than 28 weeks' gestation, yet less mature preterm infants born at the late canalicular stage of lung development continue to pose a challenge (See Figure 100-7 for stages of lung development). Many infants with CLDI go on to have long-term respiratory sequelae; however,

### BOX 100-8 NIH Consensus Definition of BPD: Jobe and Bancalari

BPD is defined as the need for supplemental oxygen for at least 28 days after birth, and its severity is graded according to the respiratory support required near term. Grading at 36 weeks post menstrual age for infants born at <32 weeks or at 56 days of life of infants born at ≥32 weeks.

- Mild:  $\text{FiO}_2$  0.21
- Moderate:  $\text{FiO}_2$  0.22–0.29
- Severe:  $\text{FiO}_2$  ≥0.30 or continuous positive airway pressure or mechanical ventilation

prolonged oxygen dependency in the neonatal period does not predict long-term respiratory outcome. Late respiratory symptoms and pulmonary function abnormalities may appear even in patients who did not require prolonged oxygen supplementation as neonates.

### Incidence

The incidence of bronchopulmonary dysplasia varies with gestational age, respiratory disease and illness severity, duration of oxygen and ventilatory support requirement, and the fractional inspired oxygen concentration needed to maintain  $\text{SpO}_2$  >90%. In a study from 2007 by Fanaroff and colleagues, the incidence of BPD when defined as an oxygen requirement at 28 days of age was 42% (BW 501–750 g), 25% (BW 751–1,000 g), 11% (BW 1,001–1,250 g), and 5% (BW 1,251–1,500 g), respectively, for the birth-weight categories noted. The majority of BPD occurs in infants with a birth weight less than 1,250 grams. Application of a definition that assesses the adequacy of oxygenation and ventilation at 36 weeks postmenstrual age and the level of the infant's need for supplemental oxygen and/or ventilatory assistance reduces the incidence by 10%.

### Pathology

Classic (old) BPD, seen mostly during the 1980s and early 1990s, was characterized by heterogeneous airway injury, smooth-muscle hypertrophy, and areas of parenchymal lung fibrosis alternating with areas with emphysematous changes. Pathologic findings of new BPD in the lung reveal more uniform inflation and less fibrosis with the absence of small and large airway epithelial metaplasia and smooth-muscle hypertrophy compared to classic BPD. The pulmonary vasculature is dysregulated in new BPD; vascular changes observed include marked angiogenesis, abnormal distribution of alveolar capillaries, prominent corner vessels with variable capillary density in adjacent alveoli, and vessels that are more distant from the air surface.

### Pathophysiology

Bronchopulmonary dysplasia has a complex, multifactorial etiology. Depending on the timing, extent, and duration of exposures, different patterns of pulmonary damage may occur (Figure 100-5). Within

**Table 100-3** Comparative Differences Between Classic and New BPD

	<b>CLASSIC BPD (Northway 1967)</b>	<b>NEW BPD (90s–current)</b>
Patients	Large preterm	Extremely low birth weight
Prenatal steroids	No	Yes
Surfactant	No	Yes
Initial ventilation	Aggressive, high O <sub>2</sub>	Gentle, low O <sub>2</sub>
<b>EVOLUTION</b>		
	Severe RDS	Mild to moderate RDS
	Severe CLD	Honeymoon period
	Respiratory/heart failure	Worsening: ductus/infection
<b>COMPLICATIONS</b>		
	Ductus arteriosus	Ductus arteriosus
	Infections	Infections
	Air leaks	Apnea, poor respiratory effort
	Cor pulmonale	
<b>RADIOLOGY</b>		
	Severe RDS	Mild RDS
	Condensations (PDA, edema, hemorrhage)	Almost normal/PDA
	Bubble-like	Hazy
	Hyperinflation/fibrosis/CHF	
<b>PATHOLOGY</b>	<b>See Figure 100-5</b>	<b>See Figure 100-6</b>
	Atelectasis, edema, Fibrosis/emphysema	Minimal airway lesions
	Smooth muscle disease	Pulmonary edema
	RVH	Arrest of alveolarization
Incidence	Decreasing	Increasing
Present distribution	<1/4	>3/4
Treatment	Ventilator	Oxygen/CPAP

**Figure 100-5** Radiologic findings in classic BPD.**Figure 100-6** Radiologic findings in new BPD.

1 and 4 days after preterm birth, inflammatory biomarkers (chemokines, adhesion molecules, pro- and anti-inflammatory cytokines, proteases and their inactivated inhibitors, and growth factors) have complex interactions that alter subsequent lung maturation. An imbalance between pro- and anti-inflammatory cytokines released secondary to antenatal and postnatal factors leads to activation of the cellular death

pathways in the lung, which is followed by healing or repair. The latter is characterized by impaired alveolarization and dysregulated angiogenesis, which lead to fewer, larger, more simplified alveoli and a dysmorphic pulmonary vasculature, the pathologic hallmarks of BPD.

Thus, chronic lung disease among very preterm infants is not simply synonymous with ventilator-induced

**Figure 100-7** Stages of lung development and types of injury. (From Baraldi, E, Filippone, M. Chronic lung disease after premature birth. *N Engl J Med.* 2007;357:1946–1955 Copyright © Massachusetts Medical Society. Reprinted with permission.)

damage associated with high concentrations of supplemental oxygen or stretch injury caused by the need for large tidal volumes (or high peak inspiratory pressures), but the final result of a range of complex insults including intrauterine inflammation, postnatal infection, lung immaturity, the effects of the patent ductus arteriosus, resuscitation maneuvers, and ventilator-associated injury. Genetic factors have been implicated in the severity of acute respiratory disease as well as the development of BPD. Additionally, inadequate nutrition is thought to lead to decreased alveolar development, impaired surfactant production, and a catabolic state that inhibits growth and repair of the premature lung. The heterogeneous damage to airways and lungs results in marked ventilation-perfusion (V/Q) mismatch. Lung compliance is reduced secondary to fibrosis and edema. Tracheobronchomalacia and increased airway resistance of both small and larger airways is common. As the course of BPD progresses, initial low lung volumes secondary to atelectasis are often at least partially replaced by hyperinflation from air trapping caused by airway inflammation.

### Management

**IN-HOSPITAL (NICU) CARE.** In-hospital management of infants with BPD requires a coordinated approach that minimizes the duration of mechanical ventilation, using noninvasive respiratory support to avoid ventilator-induced lung injury (barotrauma and volutrauma), which, in turn, reduces the incidence of hyperoxemia and hypocapnea. Careful fluid management and bronchodilator therapy can improve lung function and reduce the need for supplemental oxygen and high ventilator settings, even though it will not change the ultimate course of these infants. A trial of diuretic therapy is often added to the infant's medication regimen although there is limited evidence of efficacy. Among the available interventions, antenatal steroids, caffeine (recently demonstrated to be efficacious in the

prevention of BPD in addition to its known benefit in ameliorating apnea of prematurity, vitamin A (currently in short supply in the United States), and surfactant have the best risk-benefit profile. Postnatal corticosteroids also improve lung function and accelerate weaning from oxygen and mechanical ventilation, but their use during the first weeks of life is associated with worsened neurological outcome. Thus, systemic postnatal corticosteroids should be reserved for use only in ventilated infants who cannot be weaned from the ventilator.

Treatment with diuretics and bronchodilators has been used for symptomatic management of BPD, but the studies have shown that responses to these medications are variable and transient. Use of inhaled steroids has also been evaluated in an effort to gain the benefits of corticosteroids and minimize unacceptable systemic side effects. The trials did not demonstrate significant change on the BPD rate at 28 days of age or at 36 weeks' PMA regardless of whether the therapy was given early (<7 days) or late (>7 days). Adequate nutrition plays an important role in lung injury protection and recovery. Infants with severe BPD often develop pulmonary hypertension (PH) and should be evaluated periodically for PH as this significantly increases the risk of late and postdischarge mortality; these infants may benefit from the use of pulmonary vasodilators. Use of inhaled nitric oxide for prevention of CLD of infancy has not been validated in clinical trials. Recent insights into stem cell biology have revealed the therapeutic potential of these cells to repair damaged organs, including the lungs. In combination with strategies that already exist, cell-based therapies may allow improvements in survival with very limited disability.

**POST-DISCHARGE CARE.** Outpatient management must be carefully planned, coordinated, and carried out by experienced multidisciplinary teams. Social and financial issues must be addressed with the family

and caregivers. Maintenance of oxygenation and proper nutritional support are critical aspects in the postdischarge management of these infants. Home oxygen and mechanical ventilation therapy are used commonly after discharge and require specialized staff and equipment. The AAP Committee on Fetus and Newborn report on Hospital Discharge of the High-Risk Neonate provides guidance about discharge planning and follow-up care needs. Up to two-thirds of infants with BPD continue to have growth failure after discharge. Among the explanations for this observation are the infant's poor ability to feed orally, the occurrence of gagging, choking, and vomiting, gastroesophageal reflux, and other issues related to oromotor coordination. Increased metabolic demands can also cause growth failure. Metabolic bone disease, ranging from osteopenia to nutritional rickets, results from chronic or prolonged diuretic use. In addition, these infants are at higher risk for nephrocalcinosis and abnormal dentition, with tooth enamel hypoplasia also the result of prolonged diuretic therapy and inadequate mineral intake.

The respiratory syncytial virus (RSV) prophylaxis is recommended for all children less than 2 years of age who have required medical therapy of any chronic lung disease within 6 months prior to the start of RSV season. Preterm infants, especially those with BPD, are at increased risk for significant morbidity and mortality from influenza virus infection. Administration of influenza vaccine to all caregivers and to the infant after 6 months of age is recommended. Avoidance of second hand smoke should be explained to the parents. Infants with BPD have higher rates of rehospitalization (up to 50%) in the first year of life. Respiratory symptoms in patients with BPD may persist beyond the first 2 years of life into the preschool years, adolescence, and early adulthood. Although preterm infants have an increased risk of neurodevelopmental impairment, BPD is an additional risk factor. Readers are also referred to the guideline issued by American Thoracic Society on the Care of the Child with Chronic Lung Disease of Infancy and Childhood.

Most preterm neonates experience a relatively benign respiratory course, but in some patients the disease progressively worsens and culminates in severe respiratory failure, pulmonary hypertension, and in some cases right heart failure. Further intensive care may prolong a distressing death rather than offer any hope of survival. An end-of-life decision may be made after discussions with parents. Assisted ventilation may be withdrawn, or care redirected to withhold further episodes of assisted ventilation.

## APNEA IN NEWBORNS

### *Definition and Fundamentals*

Apnea may occur in all infants and is considered normal if it occurs infrequently, is brief, and is not associated with any underlying conditions or other signs.

Apnea of prematurity (AOP) is a significant clinical problem manifested by an unstable respiratory rhythm reflecting the immaturity of respiratory control systems. It is defined as cessation of breathing

that lasts for at least 20 seconds. All apneic episodes are not associated with cessation of breathing, and some of these episodes occur in the presence of breathing efforts but are associated with airway obstruction and cessation of airflow. On the basis of respiratory efforts and airflow, apnea has been classified as central, obstructive, or mixed. Mixed apnea constitutes most apneic episodes. Definitions of terminology are found in Box 100-9. Gastroesophageal reflux (GER) has been implicated as a cause of apnea in premature infants for decades. Yet, there has been no compelling evidence supporting a causal relationship between them. Further, antireflux medications do not reduce bradycardia episodes in preterm infants with GER. The triad of apnea, bradycardia, and oxygen desaturation occurs frequently in NICUs. Prolonged apnea may occur as a nonspecific sign of illness in both full-term and premature infants. Box 100-10 lists common conditions associated with apnea in neonates. (See also Chapter 337, Sudden Unexpected Infant Death, and Chapter 217, Apparent Life-Threatening Events.)

### *Pathophysiology*

The neuronal mechanisms leading to apnea are still not well understood. Neonatal respiratory rhythm generation is modulated by afferent signals and is the result of integration of signals from peripheral and central chemoreceptors, airway afferents, and state-dependent controls. Ventilatory responses to hypoxia and hypercarbia are impaired, and inhibitory reflexes are exaggerated in the neonate. These unique characteristics predispose the neonate to the development of apnea.

### *Evaluation*

Evaluation of the neonate who exhibits apnea is warranted if apnea develops within 24 hours of birth; if the infant is born after 36 weeks' gestation or requires vigorous resuscitation; if the episode is preceded by or associated with marked cyanosis, pallor, or change in muscle tone; or if the episodes become more frequent and increase in severity. The specific diagnostic tests are chosen based on the newborn's gestational and postmenstrual age, presenting symptoms and physical examination, underlying medical problems, and extent of resuscitation or intervention required to stabilize the newborn. Typical testing of a symptomatic neonate with unexplained apnea, bradycardia, or cyanosis includes a complete blood count, glucose and electrolyte determinations, sepsis evaluation (blood, urine, and cerebral spinal fluid cultures), and continuous multichannel recording with esophageal pH monitoring. A thorough review of the maternal history for evidence of medication use that can induce fetal CNS and respiratory depression (over-the-counter products [including herbal agents], illicit drugs, or prescribed medications and labor pain relief) is necessary. Consideration should also be given to sending a sample of the newborn's urine for toxicologic testing for drugs of abuse based on the newborn's signs and clinical history. (See Chapter 104, Prenatal Drug Use: Neonatal Effects and the Drug Withdrawal Syndrome.) If seizures or other CNS abnormalities are suspected, then the newborn should undergo a

**BOX 100-9 Apnea Terminology**

- *Pathological apnea* is apnea exceeding 20 seconds' duration or apnea of shorter than 20 seconds' duration accompanied by bradycardia, pallor, cyanosis, hypotonia, or oxygen desaturation. Apnea is classified as *central*, *obstructive*, or *mixed*.
  - *Central apnea* is the cessation of both airflow and respiratory effort.
  - *Obstructive apnea* is the cessation of airflow in the presence of continued respiratory effort.
  - *Mixed apnea* contains elements of both central and obstructive apnea, either within the same apneic pause or at different times during a period of respiratory recording. It may start as an obstructive apnea but is followed by central apnea.
- *Periodic breathing* is a respiratory pattern characterized by 3 or more consecutive respiratory pauses that are greater than 3 but less than 20 seconds in duration separated by less than 20 seconds of breathing between each pause. Periodic breathing is centrally mediated as a result of immaturity of the central nervous system respiratory control center.
- *Apnea of prematurity* usually begins after the first day of life and resolves when the infant reaches 37 weeks' postmenstrual age. AOP may occasionally persist to 44 to 48 weeks' postmenstrual age. It is defined as cessation of breathing that lasts for at least 20 seconds.
- *Apnea of immaturity* occurs in infants who are more than 37 weeks' gestation. No specific cause is identified in these infants.
- *Apparent life-threatening event* refers to an event that is characterized by some combination of apnea, color change (pallor, cyanosis), choking, or gagging and marked change in muscle tone (limp or hypotonic or arching or hypertonic).

**BOX 100-10 Common Conditions Associated With Apnea in Neonates****ACUTE CONDITIONS**

- Airway obstruction
- Neck flexion
- Laryngospasm
- Structural abnormality—glossoptosis, laryngomalacia, tracheomalacia
- Central nervous system disorders
- Intracranial hemorrhage
- Seizures
- Hypoxic ischemic injury
- Congenital malformations of the brain—Arnold-Chiari malformation
- Drugs administered to the mother or to the baby
  - Narcotics or central nervous system depressants
  - Prostaglandin E<sub>1</sub>—used to maintain patency of the ductus arteriosus in infants with suspected duct-dependent congenital heart disease
- Infection
  - Sepsis, meningitis, necrotizing enterocolitis
  - Respiratory syncytial virus infection, pertussis, infantile botulism

- Impaired oxygenation, hypoxemia, severe anemia, and shock or marked systemic-to-pulmonary circulatory shunt (eg, patent ductus arteriosus)
- Metabolic disorders
  - Hypoglycemia
  - Hypercalcemia
  - Hyponatremia, hypernatremia
  - Hyperammonemia—inborn errors of metabolism
  - Postoperative status following general anesthesia
  - Thermal instability (ie, rapid increase or decrease of temperature)

**CHRONIC CONDITIONS**

- Chronic lung disease
- Congenital central hypoventilation syndrome (formerly known as *Ondine curse*)
- Gastroesophageal reflux disease
- Marked anemia

Adapted from Spitzer A. Apnea syndromes. In: Donn SM, Sinha SK (eds). *Manual of Neonatal Respiratory Care*. 2nd ed. St Louis, MO: Mosby; 2006.

cranial ultrasound and MRI of the brain as well as have an electroencephalogram performed. If a dysrhythmia is suspected, then the newborn will require chest radiograph, electrocardiographic, and Holter monitoring studies. The newborn with a choking episode will benefit from evaluation of the airway and feeding skills by a speech pathologist and ENT specialist and evaluation for the presence of symptomatic gastroesophageal reflux disease. Subspecialist consultations may include cardiology, neurology, pulmonary, or other specialists

as needed based on the newborn's clinical condition. In cases in which apnea remains unexplained, infant polysomnography, if available, can be useful in helping to determine etiology and management.

**Management**

The initial nursery management of the neonate with apnea will include specific therapies needed to reestablish adequate oxygenation and ventilation as well as cardiac and hemodynamic stability. Treatment may

range from simple tactile stimulation and supplemental oxygen to intubation and assisted ventilation. Pharmacologic therapy will be based on the assessment of the condition causing the apnea and may include methylxanthines, antiepileptic drugs, or medications for correcting metabolic abnormalities. CPAP is an effective nonpharmacologic therapy.

See Chapter 337, Sudden Unexpected Infant Death, for treatment guidance, including indications for methylxanthines therapy and home monitoring.

## OTHER CAUSES OF RESPIRATORY DISTRESS IN NEWBORNS

### Pulmonary Air Leak Syndrome: Pneumomediastinum and Pneumothorax

Pulmonary air leak is caused by alveolar rupture with leakage of air into extra-alveolar spaces within the lung. Air leaks occur more commonly during the newborn period than at other times in life. Forms of air leak include pneumothorax, pneumomediastinum, pulmonary interstitial emphysema, pneumopericardium, and, less frequently, pneumoperitoneum and subcutaneous emphysema. Figure 100-8 depicts various forms of air leak.

#### Pneumothorax

Pneumothorax is one form of air leak syndrome that may occur in neonates either iatrogenically or spontaneously. Pneumothoraces may remain undetected in asymptomatic neonates or may cause respiratory distress. Several factors may cause a pneumothorax, including overly vigorous stimulation and resuscitation at birth, RDS, MAS, pneumonia, pulmonary hypoplasia, and assisted ventilation (CPAP and positive pressure ventilation). Generalized air trapping or uneven ventilation leads to overdistention of the lung and predisposes the infant to alveolar rupture with dissection of air along the perivascular or peribronchial tissue toward the hilum, producing a pneumomediastinum, or into the pleura, thereby causing a pneumothorax. Figure 100-5 depicts the forms of air leak.

The incidence of spontaneous pneumothorax varies from 0.3% to 1.3% based on clinical symptoms or radiographic findings. A spontaneous pneumothorax may result from rupture of alveoli secondary to high inspiratory pressures needed to expand uninflated lungs. The incidence of air leak is higher among all gestational age groups of premature infants as a result of their increased risk for lung disease and need for resuscitation and assisted ventilation.

A newborn who develops a pneumothorax may exhibit signs such as tachypnea, grunting, pallor, or cyanosis. Physical examination may reveal chest asymmetry with enlargement on the affected side, decreased breath sounds on the side with the pneumothorax, and a shift of the maximal cardiac impulse away from the affected side. A newborn who develops a tension pneumothorax may deteriorate rapidly, exhibiting bradycardia, hypotension, and hypoxemia caused by decreased venous return to the heart, thereby causing a drop in cardiac output. If a pneumothorax is suspected, then transillumination of the

**Figure 100-8** Air leak syndrome. (From Aly H. *Respiratory disorders in the newborn: identification and diagnosis*. *Pediatr Rev.* 2004;25(6):201–208.)

chest is a useful technique for immediate diagnosis. Neonates diagnosed with an air leak, whether a pneumothorax or pneumomediastinum, should be admitted to the NICU for further monitoring and treatment.

#### Pneumomediastinum

Although most newborns with a pneumomediastinum are not symptomatic, newborns with larger collections of mediastinal air exhibit tachypnea and cyanosis. The heart sounds may sound distant on auscultation. A chest radiograph will confirm the presence of a pneumothorax and other forms of air leak (Figure 100-9 and Figure 100-10). If the infant is stable, without signs of respiratory distress or a continuous air leak, and the pneumothorax is isolated and small, then the infant can be monitored closely without specific intervention. Administration of 100% oxygen to a term or late preterm infant with an air leak accelerates the resolution of pneumothorax. Oxygen should be administered for 8 to 12 hours and the chest radiograph repeated after oxygen therapy. Most infants can be managed conservatively. Thoracentesis is necessary when the infant has a tension pneumothorax or requires ventilation. A thoracostomy, or chest tube, is placed into the anterior pleural space and connected to an underwater seal with continuous-suction pressure of 10 to 15 cm H<sub>2</sub>O. The chest tube remains in place until the air leak has resolved.

## DISORDERS OF LUNG DEVELOPMENT

Congenital errors in lymphatic development are a group of rare conditions that result in primary pulmonary lymphatic disorders and are often misdiagnosed. The constellation of conditions includes lymphangiomas, lymphangiectasis, lymphangiomatosis, and lymphatic dysplasia syndrome. Pulmonary lymphangiectasia is caused by pathologic dilation of the lymphatics and has primary and secondary forms. The primary, or congenital, form occurs in neonates, is typically fatal, and is presumed to result from failure of the pulmonary interstitial tissue to regress. This form results in dilation of the lymphatic capillaries in the developing lung. Secondary lymphangiectasia in neonates is a complication that may occur after surgery, infection, or trauma. Infants with total anomalous pulmonary venous return or hypoplastic

**Figure 100-9** Anterior-posterior and lateral chest radiograph: full-term newborn with respiratory distress caused by right-sided pneumothorax. Note the flattening of the diaphragm and shift of the cardiothymic silhouette into the left hemithorax.

**Figure 100-10** Full-term infant with large pneumomediastinum: characteristic halo around the heart with lifting of the right lobe of the thymus on the anterior-posterior view and lucency in the mediastinal space on the lateral film.

left heart syndrome may develop dilated lymphatics as a result of increased lymphatic circulation.

### Lymphatic Dysplasia Syndrome

Lymphatic dysplasia syndrome is a heterogeneous group of disorders that includes idiopathic or primary lymphedema and congenital chylothorax. The neonatal form of primary lymphedema is termed *lymphedema congenita*.

Abnormal lymphatic development is associated with genetic disorders and variable inheritance patterns. Most chylous effusions in neonates are congenital.

Treatment is determined by the underlying condition. Congenital lymphangiomas do not resolve spontaneously and require resection or sclerosis. Congenital chylothorax and lymphangiectasis are treated with a combination of a high-protein, low-fat

diet that provides medium-chain triglycerides as the fat source. Portagen is the usual infant formula used for infant nutrition. Supplemental vitamins are also needed. Large pleural effusions need drainage and may require chest tube placement, if persistent.

### **Congenital Diaphragmatic Hernia**

Congenital diaphragmatic hernia (CDH) is a developmental abnormality of the diaphragm that allows abdominal organs to herniate into the chest. CDH occurs in 1 in 2,000 to 4,000 live births and has a male predominance among affected infants. Newborn infants typically show signs of respiratory distress in the delivery room or during the first hours of life. The degree of respiratory distress will vary with the severity of the defect and degree of pulmonary compromise as a result of lung hypoplasia. The most common defect responsible for development of CDH is failure of the posterior growth of the diaphragm at the left Bochdalek foramen. This defect occurs at approximately 8 weeks' gestation during embryogenesis. The extent of abdominal organ herniation into the chest will influence the severity of lung hypoplasia and severity of infant symptoms. Lung hypoplasia is most severe on the side with the hernia, but it may also involve the contralateral side. Although most CDH involves the left-sided diaphragm, right-sided lesions occur in approximately 11% of affected infants. Right-sided lesions tend to be less severe, given that the liver prevents the other abdominal organs from migrating into the chest. Bilateral diaphragm involvement occurs infrequently (2% of patients with CDH). Pulmonary hypoplasia predisposes infants born with CDH to the development of persistent pulmonary hypertension and respiratory failure.

Physical examination is notable for a barrel-shaped chest with a scaphoid abdomen. Breath sounds are absent on the affected side, and the heartbeat is displaced to the right as a result of mediastinal shift to the right. Fifty percent of infants with CDH have associated anomalies, including chromosomal abnormalities, congenital heart disease, and neural tube defects. Many infants with CDH are diagnosed prenatally. (See Chapter 82, Prenatal Diagnosis, and Chapter 83, Fetal Interventions.) Among cases that have not been diagnosed through prenatal ultrasonography, the diagnosis is confirmed by chest radiograph. Characteristic findings include herniation of the abdominal contents (intestine, liver, and spleen) into the chest. The heart and mediastinum are displaced, and the involved lung appears small.

Initial treatment involves stabilization of respiration with support for hemodynamic and cardiac function as needed. Neonates with a prenatal diagnosis of CDH should be immediately intubated (see Chapter 108, Surgical Emergencies of the Chest and Abdomen in the Newborn). Low-volume ventilation strategies using higher ventilation rates are used to minimize lung injury. The PaO<sub>2</sub> should be maintained above 55 mm Hg (oxygen saturation >90%), and mean arterial blood pressure should be above 50 mm Hg to reduce right-to-left shunting that will promote pulmonary hypertension. A nasogastric tube should also be placed expeditiously to reduce intestinal distention

because this will further compromise respiratory function. Maintaining adequate oxygenation, blood pressure, and acid-base status are critical steps in the early care of infants with CDH. Adjunctive therapies used with surgical repair include high-frequency ventilation, inhaled nitric oxide, and ECMO. Before initiating ECMO, infants require a full evaluation that includes echocardiography, cranial and renal sonography, and an electroencephalogram. Eligibility criteria for ECMO therapy require an infant to be older than 34 weeks' gestation with a weight above 2,000 g. Infants cannot have more than a grade 1 intraventricular hemorrhage or any congenital or chromosomal anomalies. Survival rates among neonates deemed surgical candidates are 60% to 80% (see Chapter 116, Health and Developmental Outcomes of Selected Medically Complex Neonates).

Other developmental lung anomaly lesions should also be considered when a CDH is suspected prenatally. These congenital lung masses, often identified as echogenic structures on prenatal sonography, are congenital pulmonary airway malformation (CPAM), congenital lobar emphysema (CLE), pulmonary sequestrations, and bronchogenic cysts.

### **Congenital Pulmonary Airway Malformation**

Congenital pulmonary airway malformation is a rare anomaly that is estimated to occur at a rate of 1 in 25,000 to 35,000 pregnancies involving abnormal lung branching. The resulting hamartomas are composed of cystic and adenomatous overgrowth of the terminal bronchioles. CPAMs typically connect to the tracheobronchial tree and may be found in any lobe of either lung. The connecting bronchi are typically abnormal. Four types of CPAM have been identified, and these are classified depending on the affected area of the tracheobronchial tree and the stage of lung development when the abnormality occurs. The occurrence of CPAM is sporadic, has no racial preference, and affects male and female infants equally. Hydrops may occur in up to 40% of infants with a CPAM. Serial prenatal sonography has shown that nearly 60% of CPAMs will regress over the period of gestation (see Chapter 108, Surgical Emergencies of the Chest and Abdomen in the Newborn).

Approximately two-thirds of neonates with a CPAM will present at birth with tachypnea, grunting, retractions, cyanosis, and increased respiratory effort. The severity of the symptoms correlates with the lesion's size. The prognosis depends on the type of CPAM. Most CPAMs that occur in the neonatal period are type 1. Type 2 lesions also occur in the neonatal period but are associated with other congenital anomalies in 60% of affected infants. Type 3 CPAM is the most severe, with resultant fetal hydrops, pulmonary hypoplasia, and high mortality rate. Treatment involves resection of the CPAM postnatally.

### **Congenital Lobar Emphysema**

Congenital lobar emphysema (CLE) is typically diagnosed after birth and is characterized by air trapping with progressive hyperinflation of lobar segments of the lungs that leads to airway obstruction. It is a rare malformation that seems to have a male predominance

and commonly involves the left upper lobe. The reported prevalence rate is 1 in 20,000 to 30,000 births. Causes can include extrinsic or intrinsic bronchial cartilage deficiencies or dysfunction, as well as abnormal mucosal folds contributing to obstruction, although in the majority of cases, no abnormalities are found. Anomalous cardiopulmonary vascularities such as PDA, pulmonary artery sling, and anomalous pulmonary venous return, or more rarely bronchogenic cysts, esophageal duplication cysts, teratoma, neuroblastoma, and mediastinal cysts, have been described as causes of extrinsic obstruction. Most infants with CLE have symptoms by 6 months of age. Up to one-third of affected infants exhibit symptoms at birth, and 50% have symptoms by 1 month of age. Respiratory distress may be mild or rapidly progressive.

Physical examination is notable for tachypnea, increased work of breathing, and wheezing. Breath sounds over the involved lobe of the lung are diminished with hyperresonance on chest percussion. If mediastinal shift is present, then the cardiac impulse may be displaced. Some infants will have associated congenital anomalies affecting the heart, kidneys, gastrointestinal tract, musculoskeletal system, and skin. Difficulty with weight gain caused by poor feeding and recurrent pneumonias may comprise the presenting symptoms in the infant with a milder form of CLE. Diagnostic imaging includes chest radiography and CT or MRI. On chest radiograph, the affected lobe may appear either consolidated or hyperinflated depending on the degree of lobar expansion. Additional findings include mediastinal shift with compression and atelectasis of the contralateral lung. CT scanning may be helpful in identifying the diagnosis in infants with persistent respiratory distress and is also useful in the postnatal assessment of the neonate with a prenatal sonographic finding of a pulmonary lesion. Included in the differential diagnosis of infants with CLE are pneumothorax, isolated pulmonary interstitial emphysema, CPAM, CDH, pulmonary sequestration, and bronchogenic cysts. Treatment in infants who have symptoms is resection of the affected lobe.

### Bronchopulmonary Sequestrations

Bronchopulmonary sequestrations are lobar sequestrations of abnormal, nonfunctioning lung tissue found in the lower respiratory tract. Extremely rare, sequestrations do not connect to the tracheobronchial tree, and they derive their blood flow from the systemic circulation, usually through a blood vessel originating from the aorta. Sequestrations are composed of normal lung tissue that contains both airway and alveolar elements. Sequestrations are of 2 types. Intralobar sequestrations are localized within a normal lobe of the lung but without separate pleura. They are typically located in a lower lobe and are slightly more common on the left side. Intralobar sequestrations are more common than the extralobar form of sequestration. Extralobar sequestrations are composed of lung tissue encased in its own pleura that is located outside the normal lung lobe. Lesions are more likely to be found on the left side, often located between the lower lobe and diaphragm. Male infants seem to be affected more often than female infants, and 2 out of 3 infants have associated

anomalies (CDH, pericardial defects, and anomalous pulmonary venous return). A gene has been identified that is necessary for normal airway development and branching (homeobox protein HOXB-5).

Respiratory symptoms at birth are variable and are related to the lesion's location, size, and type. Lesions may be identified on prenatal sonography. Most lesions regress over the course of gestation. If vascular compression develops because of a large lesion, then hydrops may develop. Extralobar sequestrations tend to present earlier than intralobar lesions. Chest radiographs show a sequestration as a dense mass in the thoracic cavity or lung parenchyma. Sonography will also demonstrate an echogenic homogeneous mass. CT and MRI characterize associated abnormalities and identify the aberrant arterial and venous blood supply to the sequestered lobe. Treatment involves immediate surgical resection in symptomatic infants.

Overall, disorders of lung development, particularly cystic lung masses, have a favorable prognosis among infants who do not have severe respiratory distress or hydrops. The generalized use of prenatal sonography has led to earlier and more frequent diagnosis of suspected fetal anomalies. Questions arise as to the need for postnatal evaluation of pulmonary lesions that appear to be regressing on serial fetal sonography. In addition, investigators have reported continued postnatal regression of congenital lung lesions. The current consensus is that prenatal ultrasonography is limited in its ability to assess fully echogenic lesions and that apparent involution of these lesions on prenatal sonography and postnatal chest radiography may miss residual lung lesions. Therefore, in the postnatal period, early evaluation is warranted.

### Tracheoesophageal Fistula and Esophageal Atresia

Esophageal atresia and tracheoesophageal fistula (discussed in Chapter 83, Fetal Interventions; and Chapter 108, Surgical Emergencies of the Chest and Abdomen in the Newborn) may occur as separate lesions but more often occur together. The classification is based on anatomy as well as certain features that are therapeutically important. Important features are the presence or absence of a fistula and the location of the fistula. The most common type (85%) consists of an upper esophageal segment that ends in a blind pouch, with the lower esophageal segment is connected to the trachea by a fistulous tract. The anomaly should be suspected in the presence of maternal polyhydramnios, excessive oral secretions, and choking, coughing, and cyanosis after the first feeding. Associated malformations such as cardiovascular abnormalities, imperforate anus, intestinal malrotation, and duodenal anomalies may occur. An association among vertebral anomalies, anal atresia, tracheoesophageal fistula, and radial limb dysplasia is also known as *VATER syndrome*. The diagnosis is confirmed by radiopaque catheter and observing coiling in the esophageal pouch on radiographic examination. The surgical correction is undertaken when the infant is stable. Complications include dysfunction of the esophageal motility, gastroesophageal reflux, chronic cough, wheezing, and recurrent pneumonia.

### Interstitial Lung Disease Unique to Infancy

Interstitial Lung Disease (ILD) in infants and young children is caused by a heterogeneous group of conditions characterized by impaired gas exchange and diffuse pulmonary infiltrates on chest imaging. Diffuse lung disease (DLD) can be caused by numerous diseases, including cystic fibrosis, congenital or acquired immunodeficiency, congenital heart disease, bronchopulmonary dysplasia (BPD), pulmonary infection, primary ciliary dyskinesia presenting with newborn respiratory distress, and recurrent aspiration. For neonates and infants younger than 2 years of age with the appearance of DLD on chest imaging, these causes should first be excluded as the primary diagnosis. Following this, the neonate or infant may be regarded as having ILD in the presence of at least 3 of the following: respiratory symptoms (cough, exercise intolerance, rapid breathing, difficult breathing); respiratory signs (adventitious breath sounds, clubbing of the fingers or toes, tachypnea, retractions, failure to thrive, respiratory failure); hypoxemia; chest radiograph or computed tomography (CT) scan showing diffuse abnormalities. A classification scheme that has evolved over the last decade distinguishes the causes of ILD in children (and especially infants) from the conditions that cause ILD in adults and adolescents. Categories primarily prevalent in infancy include diffuse developmental disorders of lung development, growth abnormalities reflecting deficient alveolarization, specific primary ILDs of undefined etiology (neuroendocrine cell hyperplasia of infancy, pulmonary interstitial glycogenosis) and disorders affecting surfactant protein metabolism (surfactant protein B, C, and ABCA3 mutations). The most common clinical signs among affected infants are hypoxia, tachypnea and retractions, as well as abnormal lung examination (crackles) and cough. Commonly associated abnormalities include gastroesophageal reflux, pulmonary hypertension, and failure to thrive. Expansive discussion of the spectrum of disorders that cause DLD and ILD in neonates is beyond the scope of this chapter. The discussion that follows will highlight the more common conditions responsible for DLD and ILD in neonates.

Rarely, one may encounter neonates or infants with persistent respiratory distress, and it is important to be aware of a broad group of disorders of childhood interstitial lung diseases. These include persistent tachypnea of infancy or neuroendocrine cell hyperplasia of infancy, alveolar capillary dysplasia associated with misalignment of pulmonary veins (ACD/MPV), pulmonary interstitial glycogenosis, and genetic abnormalities of surfactant function. Disorders in this category arise early in lung development and are diagnosed from lung biopsy or postmortem tissue based on histologic criteria.

Most childhood interstitial lung diseases share structural remodeling of the distal air spaces leading to impaired gas exchange.

Molecular defects are being increasingly identified. Whether mutations cause a fundamental derangement (eg, lack of surfactant protein), induce cellular stress (protein misfolding), or affect response to an environmental agent (disordered innate immunity) is likely to affect the age at presentation. Many

genetic syndromes identified in the past decade include deletions of or mutations in genes encoding proteins important in surfactant production and function (SP-B, SP-C, and ABCA3) or surfactant catabolism (GM-CSF receptor), as well as transcription factors important for surfactant production (TTF1) or lung development (Fox F1), with heterozygous deletions or loss-of-function mutations of the latter resulting in alveolar capillary dysplasia (ACD) with misalignment of the pulmonary veins.

Hereditary SP-B deficiency is usually a severe, rapidly progressive respiratory disease in newborns, often fatal by 3 to 6 months of age. The 10% to 15% of affected patients develop respiratory symptoms within the first month of life, whereas 40% develop symptoms between 1 and 6 months of life. Mutations in genes encoding 3 different proteins with important roles in surfactant function and metabolism, SP-B, SP-C, and ABCA3, result in lung disease with overlapping clinical, radiographic, and lung histopathologic features.

Mutations in the ABCA3 gene, which cause surfactant dysfunction, are currently the most common genetic cause of respiratory failure in full-term infants, with 150 distinct mutations identified.

ACDMPV is a disorder of lung development involving inadequate development of the pulmonary capillary bed, with the pulmonary veins found in the same bronchovascular bundles as pulmonary arteries rather than associated with pulmonary lymphatics. Affected infants typically present with severe pulmonary hypertension in the neonatal period that is unresponsive to medical management and ultimately fatal. Neonates with ACD may be placed on ECMO and require a lung biopsy before being taken off ECMO. Because ACD-MPV is universally fatal, lung transplantation is the only viable treatment option, but it is frequently limited because of the severity and rapidly progressive nature of the lung disease, which limits patient transport to a pediatric lung transplantation center. Once a definitive diagnosis is established, many families currently elect to discontinue support.

**Chapter 101****THE NEWBORN WITH A HEART MURMUR OR CYANOSIS***Nicole J. Sutton, MD; Christine A. Walsh, MD*

In the newborn, certain physical findings, such as heart murmur, arrhythmia, congestive heart failure, or cyanosis, lead to the suspicion of heart disease. Evaluation of these findings can be performed in the primary care setting.

**PREVALENCE OF CONGENITAL HEART DISEASE**

The prevalence of congenital heart disease in infants in the United States is approximately 5 to 8 per 1,000 live births. Of these patients, approximately 2.5 to 3 per 1,000 live births will have critical heart disease that requires an intervention in the first year of life. Virtually all pediatricians will see patients with congenital heart disease in their practice. The gender distribution is equal for congenital heart disease as a whole, but the male-to-female ratio varies widely among defects, with aortic stenosis, for example, more common in boys than in girls.

Several population-based studies have been conducted in the United States to examine the prevalence of congenital heart disease. The Baltimore Washington Infant Study (BWIS) is thought to be one of the most complete. The prevalence of congenital heart disease and associated risk factors were examined. The BWIS showed a significantly increased risk for congenital heart disease in children born to diabetic mothers (tetralogy of Fallot, truncus arteriosus), mothers with phenylketonuria, and mothers who abused alcohol (muscular ventricular septal defects). Overall, no racial differences were noted, but a subset analysis showed an increased proportion of white infants with Ebstein anomaly, aortic stenosis, coarctation of the aorta, transposition of the great vessels, and pulmonary atresia. No difference associated with the presence or lack of early prenatal care was found, most likely because the heart is completely formed by 12 weeks of pregnancy, before most women know they are pregnant and have started prenatal care. The study also showed no effect of maternal or paternal age on the prevalence of congenital heart disease. The BWIS found a significant risk for heart disease in infants with a family history of congenital heart disease, especially if the affected relative was the mother or a full sibling. A strong correlation was found between heart disease and other congenital anomalies, with 28% of all cases having a chromosomal abnormality, a heritable syndrome, or another major organ system defect. Down syndrome was the most common association, representing 9% of all infants with congenital heart disease.

**MURMURS**

Murmurs are the product of turbulent blood flow. Approximately 60% of newborns will have a murmur auscultated in the newborn period. If babies were

auscultated continuously from birth, nearly 100% of them would have the murmur of a closing patent ductus arteriosus (PDA). Most murmurs of the neonatal period are benign in nature. An important point to remember is that a newborn may have a severe heart defect, for example, transposition of the great vessels, without having a murmur.

**Benign Murmurs**

The most common benign murmur is a peripheral pulmonary stenosis (PPS) murmur. This murmur is caused by turbulence in the branch pulmonary arteries after closure of the ductus arteriosus. It is generally a grade 1/6 to 2/6 short, early to mid systolic ejection murmur heard best over the axillae or the back. This murmur can be present bilaterally or unilaterally, and it can be heard at birth or soon after. It should resolve by 6 months of age; if it does not, the infant should be referred to a cardiologist to exclude pathologic pulmonary artery branch stenosis, which may be associated with Williams syndrome or rubella syndrome.

The Still murmur can appear in neonates, although it is not as common in the newborn as it is in the older child. This early systolic ejection murmur is located at the left lower sternal border or near the apex and is distinguished by its low-pitched, vibratory, or humming quality. It sounds the same in the newborn and older child. If the pediatrician is comfortable with diagnosing a Still murmur, then these patients do not require a cardiology evaluation. The murmur is not associated with any underlying pathologic condition and typically disappears by puberty.

A common cause of a murmur in the newborn period is a PDA. The PDA murmur of a newborn is different from the *machinery-type* murmur that is described in older children because the pulmonary vascular resistance is still high in the newborn period. The murmur becomes louder and longer as the ductus closes and the pulmonary vascular resistance falls. It generally starts as a short, low- to medium-pitched systolic crescendo murmur at the left upper sternal border that radiates to the left infraclavicular area. If the ductus arteriosus remains patent, the murmur will eventually become the medium- to high-pitched continuous machinery-type murmur of the older child. The normal PDA murmur should resolve in the first few days to weeks of life. If it persists past the first few months of life, the PDA is unlikely to close on its own, and the infant should be referred to a cardiologist.

**Pathologic Murmurs**

The murmurs of congenital heart disease can be divided into 3 categories: stenosis, regurgitation, and left-to-right shunt (Table 101-1).

The intensity of a murmur is not a good marker of the severity of the cardiac disease that is producing it. For example, the small amount of flow through a very small and restrictive ventricular septal defect (VSD) is very turbulent and produces a much louder murmur than the much greater but less turbulent flow through a very large VSD, which is likely to cause congestive heart failure. This feature is in sharp contrast to the murmurs of outflow tract obstruction, which become increasingly louder with increasing degrees

**Table 101-1** Pathologic Murmurs

LESION	PHYSICAL FINDINGS	ELECTROCARDIOGRAM	CHEST RADIOGRAPH
<b>STENOSIS</b>			
Aortic stenosis	Grade 2/6 to 5/6 SEM at RUSB ± Systolic ejection click ± Thrill at suprasternal notch Radiates to carotids	LVH	Dilated aorta Normal PVMs
Pulmonic stenosis	Grade 2/6 to 5/6 SEM at LUSB ± Ejection click ± Thrill at LUSB Radiates to back	RVH, ± RAD	Dilated MPA Normal PVMs
<b>REGURGITATION</b>			
Mitral regurgitation	Grade 2/6 to 3/6 early systolic murmur, can be holosystolic at apex May be associated with midsystolic click if MVP Radiates to midprecordium	LAE, LVH	LAE, LVE
Tricuspid regurgitation	Grade 2/6 to 3/6 early systolic murmur, can be holosystolic at LLSB	RAE, IRBBB	Normal PVMs Possible RAE when severe
<b>LEFT-TO-RIGHT SHUNT</b>			
Atrial septal defect	Grade 2/6 to 3/6 SEM at LUSB; may not be present in infant ± Widely split, fixed second heart sound	RAD, IRBBB, RVH	Normal or cardiomegaly and increased PVMs
Ventricular septal defect	Grade 2/6 to 5/6 holosystolic murmur at LLSB; murmur may not be holosystolic with small VSD ± Thrill ± Loud P <sub>2</sub>	Normal or LVH, BVH	Normal or cardiomegaly and increased PVMs

BVH, biventricular hypertrophy; ECG, electrocardiogram; IRBBB, incomplete right bundle branch block; LAE, left atrial enlargement; LLSB, left lower sternal border; LUSB, left upper sternal border; LVE, left ventricular enlargement; LVH, left ventricular hypertrophy; MDR, mid-diastolic rumble; MPA, main pulmonary artery; MVP, mitral valve prolapse; PVMs, pulmonary vascular markings; RAD, right axis deviation; RAE, right atrial enlargement; RUSB, right upper sternal border; RVH, right ventricular hypertrophy; SEM, systolic ejection murmur; VSD, ventricular septal defect.

of stenosis and turbulence. However, with a critical stenotic lesion, a complete loss of the murmur can occur because so little flow exists through the stenotic area that the turbulence generating the murmur is very low. Newborns in severe congestive heart failure may not have a murmur until cardiac output is improved with anticongestive therapy. The loudness of the murmur must be placed in the larger context of the physical examination and presentation of the infant.

The murmur of transient tricuspid regurgitation can be heard in the newborn period. The regurgitation causing this murmur is generally not caused by a structural problem of the tricuspid valve itself, but instead by poor right ventricular function from severe pulmonary hypertension, persistent fetal circulation, neonatal asphyxia, or fetal distress. It is a grade 1/6 to 3/6 medium-pitched regurgitant murmur best auscultated at the right lower sternal border. It is occasionally holosystolic and can be very prominent in the setting of severe pulmonary hypertension. This murmur is most frequently heard in the neonatal intensive care unit (NICU) and is generally not a murmur that is observed at an outpatient visit.

### Physical Examination

In a healthy newborn, peripheral cyanosis (acrocyanosis) is common. In the normal neonatal cardiac

examination, the point of maximal intensity may be at the left lower sternal border because of the hyperactivity of the right ventricle. The second heart sound may be single, and an ejection click indicative of pulmonary hypertension may be heard. Peripheral pulses are generally easy to palpate in the newborn and are accentuated in premature infants because of the lack of subcutaneous tissue.

When a murmur is heard, the examiner should analyze it in terms of intensity (grade 1/6 to 6/6), timing (systolic vs diastolic), location (of maximal intensity), transmission (eg, to the back), and quality (blowing, vibratory, harsh, or other qualities). These characteristics will suggest a differential diagnosis. For example, the Still murmur is a grade 2/6 to 3/6 vibratory, systolic ejection murmur heard best between the left lower sternal border and the apex without radiation. Abnormal physical findings that are vital to note are cyanosis, tachycardia, tachypnea, hepatomegaly, poor perfusion, and poor or discrepant pulses. These findings are discussed in more detail in the section on congestive heart failure.

### Evaluation

If a murmur or other suggestion of heart disease is present, blood pressures must be obtained in the arms and a leg to rule out a coarctation of the aorta. In a healthy child, the lower extremity blood pressures are approximately

10 mm Hg higher than the right arm pressure. In an infant, the right upper extremity and lower extremities may have a similar systolic blood pressure. The left subclavian artery can be involved in a coarctation, so the right arm blood pressure must be obtained. It is also important to obtain a left arm blood pressure because of the association of coarctation of the aorta with an aberrant right subclavian artery coming off the descending aorta below the coarctation, which would result in equal pressures in the right arm and the leg despite a coarctation. All of the blood pressures must be taken with the baby in the same state, for example, sleeping; otherwise, differences in the blood pressures may not be valid. In addition, the heart rate should be approximately the same throughout the process.

An electrocardiogram (ECG) evaluation should be performed on all patients with a heart murmur or other suggestion of heart disease. The ECG findings must be interpreted with regard to the axis of the P wave and QRS complex, right and left atrial and ventricular enlargement, ST-T changes, conduction abnormalities, rate, and rhythm. It must be read with knowledge of normal values for age because of the many changes that occur in the first weeks of life. The normal ECG of a newborn will show sinus rates of up to 180 beats per minute. The axis can be as far rightward as +180 degrees. Right ventricular dominance is normal, even to the point of an occasional neonate having Q waves in V<sub>1</sub>. The examiner should make sure that any infant with a murmur or signs of congestive heart failure is in sinus rhythm (positive P waves in leads I, II, and aVF). A superior axis (0 to -150 degrees) is consistent with an endocardial cushion defect. A positive T wave in V<sub>1</sub> after 3 days

of age and a qR pattern in V<sub>1</sub> are indicative of right ventricular hypertrophy. Specific voltage criteria exist for right and left ventricular hypertrophy at various ages. Right atrial enlargement is suggested by a P wave that is 3 mm tall or greater in any lead. In a newborn, left atrial enlargement is suggested by a P wave that is greater than 0.07 second wide, often associated with notched P waves in the limb leads and biphasic P waves in V<sub>1</sub>. An incomplete right bundle branch block can be seen with an atrial septal defect, Ebstein anomaly, or coarctation of the aorta in the newborn. A delta wave and short PR interval are hallmarks of Wolff-Parkinson-White (WPW) syndrome (Figure 101-1).

Oxygen saturation should be obtained in a preductal (right arm) and a postductal (foot) area to detect right-to-left shunting through the patent ductus arteriosus. This test is especially important in the immediate neonatal period. In addition, if the oxygen saturations are abnormal, a hyperoxia test should be performed. This test is described later in the discussion of cyanosis. A healthy 1-day-old infant may have an arterial pressure of oxygen (PaO<sub>2</sub>) as low as 60 mm Hg.

Finally, a chest radiograph is frequently taken in the neonatal period when the patient is still in the hospital. A chest radiograph is less frequently performed when a murmur is detected in an office setting than it is in the hospital setting. Useful information can be gleaned from the chest radiograph, including the size, shape, and location of the heart; the status of the pulmonary vascular markings; and on which side the aortic arch is located. However, the size of the cardiac silhouette on chest radiograph is a poor predictor of the actual heart size.

**Figure 101-1** ECG showing a short PR interval and delta waves during normal sinus rhythm (Wolff-Parkinson-White syndrome) in a newborn.

## ARRHYTHMIAS

The easiest method of differentiating rhythm disturbances is to listen with a stethoscope. Is the rhythm too fast, too slow, or irregular but close to the normal rate?

### Bradyarrhythmias

A slow heart rate is defined as being less than the fifth percentile for the age of the patient. A persistent heart rate less than 80 beats per minute is considered bradycardia in a newborn (Figure 101-2). Sinus bradycardia is seen more frequently in preterm than in term infants. Causes include maternal medication,

neonatal asphyxia, increased intracranial pressure, sepsis, hypothyroidism, hypothermia, and hyperkalemia. The underlying cause of sinus bradycardia must be discovered and treated.

After sinus bradycardia, the most common cause of a slow heart rate in a neonate is congenital complete heart block (Figure 101-3), which is usually first noted during routine prenatal care. Congenital complete heart block is generally associated with maternal systemic lupus erythematosus, more specifically with anti-Ro and anti-La antibodies that attack the conduction tissue of the fetal heart. No correlation has been

**Figure 101-2** ECG showing sinus bradycardia with a 1.8-sec pause followed by a junctional escape beat in a premature newborn.

**Figure 101-3** ECG reflecting complete heart block in a newborn.

**Figure 101-4** Supraventricular tachycardia in a newborn.

found between this pathologic abnormality and structural heart disease. The low heart rate is generally well tolerated, and the fetus does not usually develop hydrops. When the babies are born, they appear clinically well, with a low resting heart rate, often in the range of 60 to 70 beats per minute. They usually do not require a pacemaker in the newborn period, but they need to be evaluated by a cardiologist when they are born. A pacemaker is indicated if the QRS is wide or if the heart rate is less than 50 to 55 beats per minute in an infant with a normal heart, or less than 70 beats per minute in an infant with congenital heart disease. An echocardiographic examination should be performed after birth to evaluate structure and function, even if fetal echocardiograms were performed.

### Tachyarrhythmias

A fast heart rate is greater than the 95th percentile for the age of the child. Transient sinus tachycardia up to 190 beats per minute is often seen in healthy newborns. However, the maximal rate should not exceed 220 to 230 beats per minute in an infant. Rates above this level are not sinus because the sinus node is generally incapable of faster rates.

The most common childhood tachyarrhythmia (after sinus tachycardia) is supraventricular tachycardia (SVT), usually with a heart rate greater than 220 beats per minute (Figure 101-4). The baseline ECG can be normal, or it can have a short PR interval and delta

waves indicative of WPW syndrome that is present in 50% of newborns with SVT (see Figure 101-1). In addition to SVT, babies can also have atrial tachyarrhythmias such as ectopic atrial tachycardia, atrial flutter (Figure 101-5), and much less commonly atrial fibrillation. Other less common neonatal tachyarrhythmias are junctional ectopic tachycardia and ventricular tachycardia.

The normal QRS duration in a neonate is 70 msec or less, which is important when deciding whether a narrow- or wide-complex tachycardia is present. A QRS duration of 90 msec, which is normal for an adult, is wide for a baby and can indicate ventricular tachycardia (Figure 101-6). Ventricular tachycardia is often misdiagnosed as SVT in the newborn because of this feature. The rate of ventricular tachycardia can be as high as the SVT rate in neonates; therefore, the rate will not differentiate between the 2 tachyarrhythmias. The treatment and implications are very different for a narrow-complex SVT and a wide-complex ventricular tachycardia. In either case, a pediatric cardiologist must evaluate these patients as soon as possible because congestive heart failure can develop from a persistent tachyarrhythmia. An echocardiographic examination is required to evaluate the structure and function of the heart. Acute treatment of a tachyarrhythmia may be medical or electrical cardioversion, followed by an antiarrhythmic agent to prevent recurrence.

**Figure 101-5** ECG showing atrial flutter in a 4-month-old boy.

Radiofrequency ablation is not usually performed in newborns because the arrhythmia may spontaneously resolve, because of technical difficulties related to the size of the patient, and because of the possibility that radiofrequency lesions may expand with time in this age group.

### Irregular Rhythms

The most common cause of an irregular rhythm in the child or adolescent is sinus arrhythmia. Sinus arrhythmia is a normal finding in which a variation exists in the heart rate with respiration. A 12-lead ECG with a rhythm strip will show positive P waves of the same morphology in leads I, II, and aVF, each followed by a QRS complex. In newborns, however, an irregular heartbeat is more often caused by premature atrial or ventricular beats, which are usually single and uniform. The overall heart rate is normal. These patients

usually have structurally normal hearts. No intervention is needed, and the premature beats usually resolve with time.

Atrial premature contractions (APCs) may be conducted normally resulting in a normal narrow QRS (Figure 101-7), or they may be conducted aberrantly resulting in a wide QRS (Figure 101-8). Both normally conducted and aberrantly conducted APCs have a preceding P wave, which is different from the sinus P wave. Nonconducted (blocked) APCs have an abnormal early P wave but no QRS, and if they are frequent, they may result in a low heart rate (Figure 101-9).

Premature ventricular contractions (PVCs) are early beats that are wide and not preceded by a P wave (Figure 101-10). After a PVC, a full compensatory pause usually occurs before the next sinus beat, meaning that the length of 2 cycles, including the premature beat, is equal to that of 2 normal cycles. PVCs are considered

**Figure 101-6** ECG reflecting nonsustained monomorphic ventricular tachycardia in a newborn.

**Figure 101-7** ECG showing atrial premature contractions with normal conduction as atrial bigeminy in a newborn.

significant if they are frequent, multiform, occur as couplets or runs, or are associated with a long QT interval.

### Evaluation

When an arrhythmia is appreciated, a standard 12-lead ECG evaluation should be performed with a rhythm

strip that is 30 seconds to 1 minute long, preferably with 12 simultaneous leads. The rhythm strip is essential to diagnosis and can be obtained with all ECG machines or ordered specifically from any ECG laboratory. The rest of the physical examination of the baby with an arrhythmia is generally normal, but an

**Figure 101-8** ECG showing atrial premature contractions with aberrant conduction in a newborn.

**Figure 101-9** ECG showing blocked atrial premature contractions (down arrows) as atrial trigeminy.

association can be found with acquired heart disease or congenital heart disease. A common and important association is Ebstein anomaly of the tricuspid valve and SVT. These patients have an accessory pathway that can sometimes be manifested on the ECG as a short PR interval and delta wave of WPW syndrome (see Figure 101-1). Other associations are infection (eg, myocarditis), neurologic disease (eg, asphyxia), and metabolic disorders (eg, electrolyte abnormalities).

Infants with heart disease often decompensate with an arrhythmia. Any sign of congestive heart failure in a baby with an abnormal rhythm requires an immediate evaluation by a pediatric cardiologist.

### CONGESTIVE HEART FAILURE

Congestive heart failure (CHF) is the inability of the heart to do the work required. This inability can be caused by abnormal muscle function with

**Figure 101-10** ECG reflecting single uniform premature ventricular contractions as ventricular quadrigeminy in a newborn.

a normal workload or by an increased workload with normal muscle function. (Box 101-1 lists the causes of CHF.)

The history is critical in making the diagnosis of CHF. Babies with CHF have poor feeding; they are very hungry and start to eat ravenously but tire quickly and get very short of breath. They need to rest frequently while feeding and may want to eat again shortly afterward because they cannot ingest enough at any one sitting. A detailed feeding history should be elicited, including frequency of feedings and how many minutes each feeding lasts. Babies with CHF may also have sweating with feeds, which is a sign of how hard they are working when they feed. They need more calories than normal babies but are consuming fewer. A history of poor weight gain will be found, with head circumference and length being spared to some degree.

Signs of CHF include underweight and tachypnea. Infants may exhibit retractions, nasal flaring, and grunting. A cardiac examination may show tachycardia, a gallop, or a hyperactive or hypoactive impulse. Any rhythm disturbance must be investigated to determine whether the arrhythmia is the cause or result of CHF. Murmurs may or may not be appreciated in a baby with CHF. Some conditions causing CHF are not associated with heart murmurs. Even murmurs caused by structural heart disease may not be heard if the baby has low cardiac output; these murmurs become evident when anticongestive therapy is effective. Crackles in the lungs from pulmonary edema and hepatomegaly are presenting signs of CHF. Signs of poor perfusion include mottling, slow capillary refill, cool extremities, and poor pulses. Good upper extremity pulses and poor femoral pulses indicate a coarctation of the aorta; however, this difference may not be evident if low cardiac output is present. The examiner should feel the right brachial pulse and femoral pulse simultaneously to detect a delay, suggesting a coarctation.

A pediatric cardiologist must evaluate a baby with CHF as soon as possible. Echocardiography, ECG, and chest radiography must be performed. Some infants may need to be stabilized and transported emergently

### **BOX 101-1 Causes of Congestive Heart Failure**

#### **NONCARDIAC CAUSES**

- Birth asphyxia with myocardial ischemia
- Sepsis
- Anemia
- Hypoglycemia
- Hypocalcemia
- Adrenal insufficiency
- Maternal diabetes mellitus
- Barth syndrome
- Cerebral arteriovenous malformation

#### **PRIMARY MYOCARDIAL DISEASE**

- Hypertrophic cardiomyopathy
- Myocarditis
- Endocardial fibroelastosis

#### **ARRHYTHMIAS**

- Supraventricular tachycardia
- Ectopic atrial tachycardia
- Atrial flutter or fibrillation
- Junctional ectopic tachycardia
- Ventricular tachycardia
- Complete heart block

#### **STRUCTURAL HEART DISEASE**

- Anomalous left coronary from the pulmonary artery
- Pressure overload lesions
  - Coarctation of the aorta
  - Aortic stenosis
  - Hypoplastic left heart syndrome
- Volume overload lesions: left-to-right shunt
  - Ventricular septal defect
  - Atrial septal defect
  - Patent ductus arteriosus
  - Complete atrioventricular canal

to a tertiary-care NICU or emergency department, especially if shock is present. (See Chapter 111, Care of the Sick or Premature Infant Before Transport.)

### Abnormal Muscle Function

Abnormal muscle function in newborns may be caused by a primary cardiomyopathy (eg, myocarditis, endocardial fibroelastosis), or it can be secondary in nature. Some causes of secondary cardiomyopathy are arrhythmias (eg, tachyarrhythmias, complete heart block), metabolic disorders (eg, adrenal insufficiency, hypocalcemia, hypoglycemia, Pompe disease), sepsis, and anemia. A gallop and the murmur of mitral or tricuspid regurgitation may be heard in these patients.

### Increased Workload

The other category of patients who develop CHF have normal muscle function but have increased workload. The increased workload can be divided into pressure overload and volume overload.

#### Pressure Overload

Common causes of increased pressure work are aortic stenosis, pulmonary stenosis, and coarctation of the aorta. Hypoplastic left heart syndrome will often exhibit as a severe version of coarctation of the aorta.

Coarctation of the aorta is a stenosis of the upper thoracic aorta, usually just opposite the insertion of the ductus arteriosus (juxtaductal). Depending on the severity of the stenosis, the effect on cardiac output can vary from very minimal to severe. The degree of stenosis is hard to predict clinically or by echocardiographic evaluation before the PDA has completely closed, given that the ductal tissue can be involved in the site of the coarctation. The stenosis leads to increased pressure in the proximal aorta, causing increased systolic pressure and wall stress in the left ventricle, resulting in left ventricular hypertrophy. However, when the stenosis is severe and increases suddenly, such as occurs when the PDA closes in a patient with a critical coarctation, the left ventricular wall stress rises very sharply over a short period. The left ventricle does not have time to compensate with hypertrophy and can fail in hours or days, resulting in low cardiac output and shock. Prostaglandin is used to keep the ductus open until surgery is performed.

On cardiac examination, a suprasternal notch thrill may be present. The first and second heart sounds are generally normal. Occasionally, a systolic ejection click from a bicuspid aortic valve is heard. Some newborns have a grade 2/6 to 3/6 systolic ejection murmur at the left upper sternal border radiating to the back from the coarctation itself, but this finding is uncommon. The most prominent finding is the discrepancy between the upper and lower extremity pulses and blood pressures. In these babies, the PDA shunts right to left and represents the only source of blood flow to the lower extremities. The saturation in the feet may therefore be lower than those in the right arm while the PDA is open. When the PDA closes, the right-to-left shunt resolves, and the saturation in the feet will

be same as that in the right arm, but the perfusion will be much worse.

The ECG in the newborn is often normal without evidence of left ventricular hypertrophy. The ECG can show right ventricular hypertrophy in the neonatal period because the right ventricle is still responsible for pumping most of the cardiac output to the body through the PDA. Patients who present later with coarctation generally have a murmur or hypertension, with left ventricular hypertrophy on the ECG. They do not have as severe a coarctation and therefore still have forward cardiac output around the aortic arch without a PDA. A chest radiograph shows the nonspecific findings of cardiomegaly and increased pulmonary vascular markings. Rib notching is not present because the collateral circulation has not yet developed sufficiently.

Babies with critical aortic stenosis and hypoplastic left heart syndrome can also present in shock. In these patients, the pulses are quite thready, but the brachial and femoral pulses will be equally poor, and blood pressures will be the same in upper and lower extremities. However, some babies in shock from a coarctation will have such poor pulses that detecting a difference between upper and lower extremities is difficult. Infants with coarctation often have a normal ECG or right ventricular hypertrophy, whereas neonates with aortic stenosis will have left ventricular hypertrophy, and those with hypoplastic left heart syndrome will have decreased or absent left ventricular forces with right ventricular hypertrophy.

#### Volume Overload

The volume overload lesions are atrial septal defect, VSD, PDA, and common atrioventricular canal. VSD is discussed here because it is the most common volume overload lesion to cause CHF in infants.

VSDs are the most common form of congenital heart disease, if bicuspid aortic valve is excluded. The amount of shunting across a VSD is determined by the size of the defect and the relative resistances of the systemic and pulmonary circulations, but not the location of the VSD in the septum. CHF can occur with a moderate to large VSD.

On cardiac examination of an infant with a VSD, a systolic thrill may be palpable at the left lower sternal border. A hyperactive precordium and loud  $P_2$  are present with a large shunt. A grade 2/6 to 5/6 pansystolic or early systolic murmur is audible at the left lower sternal border. An apical diastolic rumble of relative mitral stenosis may be present with a moderate to large shunt. (For a complete discussion of VSD, see Chapter 234, Congenital and Acquired Heart Disease.)

## CYANOSIS

Cyanosis is a bluish discoloration of the skin and mucous membranes and is either peripheral (acrocyanosis) or central. Peripheral cyanosis can occur with hypovolemia or shock, but it is a common finding in healthy infants who are vasoconstricted from the cold or a fever. Circumoral cyanosis refers to bluish skin around the mouth and, if isolated in a cold baby, is of no concern. Central cyanosis requires desaturation

of 5 g/100 mL of hemoglobin and is usually not detectable until the arterial oxygen saturation is 85% or lower in an infant with a normal hemoglobin. Cyanosis can be seen at a higher level of oxygen saturation in patients with polycythemia and at a lower level in patients with anemia. Cyanosis can be difficult to detect in dark-skinned infants. The best place to assess for cyanosis is the tongue, which has a rich vascular supply and is free of pigmentation. Clubbing describes thick, wide, spoon-shaped fingertips and toes with convex nail beds; it usually does not start to develop until the child is 6 months or older.

Central cyanosis can be caused by upper airway (eg, laryngeal web) or lower airway (eg, pneumonia) disease. Upper airway disease is characterized by marked hypercarbia, inspiratory stridor, and retractions. Hypercarbia develops later in lower airway disease, and findings include tachypnea, expiratory wheezing, grunting, crackles, and retractions. Apnea or shallow irregular respirations and hypercarbia are seen in the cyanotic infant with central nervous system disease (eg, birth asphyxia). Babies with methemoglobinemia are only tachypneic; their arterial blood gas shows a normal PaO<sub>2</sub> and low oxygen saturation. In newborns with persistence of the fetal circulation, right-to-left shunting occurs through the patent foramen ovale and PDA because of persistent pulmonary hypertension, which may be idiopathic or a result of conditions such as meconium aspiration, hypoglycemia, and perinatal asphyxia.

Infants with cyanosis from congenital heart disease can be divided into those with acyanotic congenital heart disease with CHF (eg, large VSD) producing abnormal diffusion and  $\dot{V}/\dot{Q}$  mismatch in the lungs (similar to lower airway disease) and those with true cyanotic congenital heart disease with a right-to-left shunt.

Patients with a true right-to-left shunt can be differentiated with a hyperoxia test. As close to 100% oxygen as possible is administered for 10 minutes. When a right-to-left intracardiac shunt is significant, the PaO<sub>2</sub> does not usually increase to greater than

100 mm Hg, and the rise is not usually more than 10 to 30 mm Hg. However, in defects with markedly increased pulmonary blood flow, such as total anomalous pulmonary venous return, the PaO<sub>2</sub> can rise as high as 150 mm Hg.

When possible, simultaneous blood gases should be obtained from the right upper extremity and umbilical artery or lower extremity to determine the presence of a right-to-left ductal shunt. A 10- to 15-mm Hg difference between the right radial artery and umbilical artery is considered significant.

Cyanotic congenital heart defects can be divided into those with decreased pulmonary blood flow and those with increased pulmonary blood flow (Table 101-2). Defects with decreased pulmonary blood flow have in common right-sided obstruction (eg, tricuspid atresia, pulmonary atresia, pulmonary stenosis) to pulmonary flow with a right-to-left shunt through a normal patent foramen ovale or abnormal intracardiac communication (VSD). Tetralogy of Fallot will be discussed as an example. Defects with increased pulmonary blood flow have intracardiac mixing of saturated and desaturated blood, but no obstruction to pulmonary blood flow. Transposition of the great arteries will be discussed as an example.

### Tetralogy of Fallot

Tetralogy of Fallot (TOF) is the most common cyanotic congenital heart defect, representing 5% to 7% of all congenital heart disease. Most patients with TOF will exhibit symptoms in the immediate newborn period with cyanosis and a murmur. The degree of cyanosis is determined by the severity of the pulmonary stenosis. Some infants will not be cyanotic at birth but will develop increasing obstruction and cyanosis over the first year of life. Other infants have such severe cyanosis that they are dependent on the PDA for blood flow to the lungs and become severely ill when the PDA closes.

On physical examination, a systolic thrill at the left upper and midsternal borders and an increased right

**Table 101-2** Cyanotic Congenital Heart Disease

DISEASE	ECG	CHEST RADIOGRAPH	
		HEART SIZE	PVMs
Tetralogy of Fallot	RVH, RAD	Boot-shaped heart	Decreased
Tricuspid atresia	Superior axis, decreased RV forces, LVH	Normal to slightly increased heart size	Decreased
Pulmonary atresia	Normal axis, decreased RV forces; LVH	Normal to slightly increased heart size	Decreased
Critical pulmonic stenosis	RAD, RVH	Normal to slightly increased heart size	Decreased
Ebstein anomaly	RAE, RBBB, delta wave of WPW syndrome	Extremely enlarged heart size (mainly from RA dilation)	Decreased
Truncus arteriosus	BVH	Cardiomegaly	Increased
TGA	RAD, RVH	Egg-shaped heart with narrow superior mediastinum	Increased
TAPVR	RAD, RVH with RSR'	Cardiomegaly	Increased

BVH, biventricular hypertrophy; ECG, electrocardiogram; LVH, left ventricular hypertrophy; PVMs, pulmonary vascular markings; RA, right atrial; RAD, right axis deviation; RAE, right atrial enlargement; RBBB, right bundle branch block; RV, right ventricular; RVH, right ventricular hypertrophy; TAPVR, total anomalous pulmonary venous return; TGA, transposition of the great arteries; WPW, Wolff-Parkinson-White.

ventricular impulse are usually present. The second heart sound is single, and a systolic ejection click may be heard. Typically a long, loud crescendo-decrescendo systolic murmur of right ventricular outflow tract obstruction is audible at the left upper and midsternal borders. The infant may be tachypneic but not particularly dyspneic, and the pulses are usually good.

The ECG will show isolated right ventricular hypertrophy with a rightward axis. A chest radiograph classically shows a boot-shaped heart with decreased pulmonary vascular markings. Approximately 25% of patients with TOF have a right aortic arch. (For a full discussion of TOF, see Chapter 234, Congenital and Acquired Heart Disease.)

### Transposition of the Great Arteries

Transposition of the great arteries (TGA) represents approximately 3% to 5% of all congenital heart defects. A strong male predominance exists in this disorder, but it is not usually associated with other congenital anomalies or chromosomal abnormalities. Newborns with TGA have severe cyanosis. The rest of the physical examination is often normal except for tachypnea. The baby may be large because TGA is found more commonly in infants of a diabetic mother. The typical patient is a *big, blue, baby boy*. Murmurs are not prominent in the absence of a VSD and pulmonary stenosis.

Initially, the chest radiograph may be completely normal. With time, the chest radiograph will show overcirculation of the pulmonary vasculature. The classic description of the heart on chest radiograph evaluation is an *egg on a string*. The ECG may be normal or show right ventricular hypertrophy.

The most classic, but infrequently seen, finding in TGA is reversed differential cyanosis, that is, greater cyanosis of the upper half of the body than the lower half of the body. This finding is caused by shunting of blood with a higher saturation from the pulmonary artery to the descending aorta through the PDA. Usually the  $\text{PaO}_2$  is less than 35 mm Hg in room air and 35 to 40 mm Hg on 100% oxygen.

## Chapter 102

# THE NEWBORN AT RISK FOR INFECTION

Tsoline Kojaoghlanian, MD

Neonatal infections can be broadly categorized as either congenital, indicating their presence at birth and likely acquisition in utero; or perinatal, indicating acquisition late in pregnancy or during the delivery. Outcomes for the neonate after infection can vary widely based on the organism involved, the time during gestation when infection occurs, and whether the mother has any protective antibodies that can provide the fetus with passive protection, reducing the disease severity for the infant.

Transplacental spread of maternal infection is the common route by which the fetus acquires infection. Placental infection is often associated with systemic illness in the neonate; thus, molecular, microbiologic, and pathologic examination of the placenta is important in the critically ill newborn. In the perinatal period, acquired early-onset infection (before 72 hours) is almost always caused by organisms acquired in the maternal birth canal. After this period, most infections are acquired through close contact with members of the baby's environment and through human milk. The manifestations of infection vary with the infecting organism. The mechanism of damage and response by the host, as well as the stage of the pregnancy, determine the effects on the neonate. Some pathogens can have deleterious effects throughout gestation. Fetal organogenesis is complete by 12 weeks' gestation; thus, damage incurred during this period will likely result in anomalies. The mother does not transfer T-cell-specific immunity, crucial in the control of many viruses, to the fetus. Maternal IgG antibodies, conversely, are transferred to the fetus and reach one-half the normal serum concentration by 30 weeks' gestation and more normal values at term. Furthermore, the transferred antibodies must be of a certain concentration to be protective. In some bacterial infections, the mother may not have enough circulating antibodies, and this factor is complicated by the fact that newborns cannot mount an antibody response to polysaccharide antigens, such as those found on bacterial capsules (eg, those of group B *Streptococcus* [GBS]). Newborns who experience a sufficient period of antigenic stimulation (usually 7–14 days) will exhibit a measurable IgM response to some viruses and parasites, which can be used diagnostically. In addition, antigen-specific T-cell responses are significantly reduced or delayed in neonates, and this also translates to delays in B-cell and antibody responses.

In the neonate, the factor associated most significantly with sepsis caused by any microorganism is low birth weight. Very low-birth-weight (VLBW) and premature infants are especially susceptible to infections. Other factors include prolonged rupture of membranes, traumatic delivery, maternal infection, chorioamnionitis, and fetal hypoxia. The incidence of

bacterial meningitis is greater in the neonatal period than in any other period in life. Furthermore, these infants are predisposed to a number of acquired infections by the use of modern neonatal intensive care techniques that include endotracheal intubation, parenteral nutrition, chronic blood vessel cannulation (umbilical, percutaneous intravenous, and other central vessel catheterization), disruption of skin integrity, delay in feeding, formula rather than human milk feedings, and administration of broad-spectrum antibiotics and other medications that alter the infant's intestinal and skin flora. Deficiencies in mucosal barrier function, and in both the innate and adaptive arms of the immune response, including serum complement components, defensins, and abnormalities in cytokine production, plus deficiencies of chemotaxis, phagocytosis, and microbial killing, contribute to the vulnerability of preterm neonates to systemic infections. Globally, the major burden of preterm birth is in the developing world, where infectious diseases such as malaria, human immunodeficiency virus (HIV), tuberculosis, and intestinal parasites cause much of the mortality and morbidity. Women and their infants also disproportionately bear the long-term consequences of sexually transmitted infections, including syphilis, herpesviruses, and *Chlamydia*.

Neonatal infections are caused by a variety of microorganisms. By convention, *congenital* infections have been assimilated into the acronym TORCH: toxoplasmosis, other agents (including syphilis, parvovirus B19, hepatitis B virus [HBV], enterovirus and HIV), rubella, cytomegalovirus (CMV), and herpes simplex virus (HSV). However, unlike most TORCH infections, which are acquired transplacentally, 90% of HSV and 80% of HIV infections are transmitted perinatally at the time of delivery. Many viruses that are transmitted from mother to child must find a way to persist in the infected mother for her to pass it on to her offspring.

Toxoplasma, CMV, rubella, and syphilis are the primary pathogens acquired in utero that result in congenital infection. Antenatal imaging has been a useful adjunct in prenatal diagnosis, and the most common fetal ultrasound findings to be associated with congenital infections are echogenic bowel, ascites, pleural effusions, cardiomegaly, and oligohydramnios; intrauterine growth restriction (IUGR) and ventriculomegaly coexist with other features. The yield of screening

infants born with IUGR or ventriculomegaly for all TORCH serology is low, even among infants screened for TORCH because of the presence of thrombocytopenia, neutropenia, direct hyperbilirubinemia, or dysmorphic features. Maternal hypertensive disorders of pregnancy, smoking, and drug or alcohol use are more likely culprits for IUGR. In all circumstances, postnatal screening for congenital infections must be cost-beneficial and -effective to be implemented. Table 102-1 summarizes the estimated relative incidence of some neonatal infections.

## CONGENITAL INFECTIONS

### Cytomegalovirus

CMV is the most common congenital infection and the leading infectious cause of damage to the developing fetus in developed countries. In the United States, 35,000 newborns (0.7%–1% of births) are infected annually, 6,700 of whom will have CMV-related damage. Among all children with bilateral moderate to profound sensorineural hearing loss (SNHL), an estimated 20% are attributable to congenital CMV infection. As is true of all herpesviruses, after primary infection, CMV establishes latency and can replicate actively at epithelial sites throughout the lifetime of the host. Intrauterine infection after primary maternal infection is 40% to 50%, compared with 0.5% to 2% after reactivation of latent virus. The existence of multiple strains of the virus is responsible for a small number of congenital infections acquired by reinfection with a new strain during pregnancy. CMV infects placental cytotrophoblasts and is transferred to the fetus through placental infection. The mechanisms by which CMV injures the fetus likely include a combination of direct fetal injury induced by pathologic, virally encoded gene products, an inability of the maternal immune response to control infection, and the direct effect of infection on placental function.

CMV is transmitted via breastfeeding, close contact with young children, and sexual contact. Improved hygiene and formula feeding in the developed world have delayed acquisition of CMV to the childbearing years. From 1988 to 2004, the overall age-adjusted CMV seroprevalence for individuals 6 to 49 years old in the United States remained stable at 50%. CMV seroprevalence is higher among non-Hispanic black and

**Table 102-1** Estimated Relative Incidence of Some Neonatal Infections (per 100,000 Live Births) in the United States

INFECTIOUS AGENT	OVERALL INCIDENCE PER 100,000 LIVE BIRTHS	SYMPTOMATIC AT BIRTH
Cytomegalovirus	1,000	100
<i>Toxoplasma gondii</i>	10–40	2–8
Rubella virus	<1	<1
Varicella virus	<1	<1
<i>Treponema pallidum</i> (syphilis)	13	4
Human Immunodeficiency Virus (HIV)	5	<1
Herpes simplex virus	10–40	10–40
Group B <i>Streptococcus</i>	30–50	30–50

Hispanic women compared with non-Hispanic white women, and in those who are older, foreign-born, have low household income, and have high household crowding. Infection rate is 2.5% during pregnancy, 5.5% between pregnancies, and 10% per year in women of childbearing age who are child care employees.

The highest risk of transplacental transmission resulting in congenital infection is during the third trimester of pregnancy (75%); however, most of these neonates will be born asymptomatic. On the other hand, 25% of newborns who acquire infection during the first trimester will have central nervous system (CNS) involvement. Overall, 90% of infected newborns will be asymptomatic, but 10% to 15% of these asymptomatic infants will still develop SNHL and, less commonly, other CNS sequelae. Of the 10% of newborns who have symptoms at birth, 20% will die; 70% will have hearing loss with varying degrees of developmental delay, motor or cognitive impairment, and seizures; and only 10% will survive without sequelae. Hence, overall, 20% of infected infants will have some degree of hearing or CNS disability. Symptomatic disease may manifest as premature delivery (35%), IUGR (50%), microcephaly (55%), periventricular calcifications, polymicrogyria, jaundice (65%), petechiae (75%), hepatosplenomegaly (60%), thrombocytopenia (77%), hyperbilirubinemia (70%), and mild hepatitis (85%). CMV has a predilection to the rapidly multiplying cells of the germinal matrix. If overt CNS findings are present at birth, almost all will have major neurodevelopmental sequelae. Microcephaly is the most specific predictor of intellectual and motor disability, followed by abnormal computed tomographic scan findings. The developing CNS remains vulnerable to damage from persistent virus replication after birth. SNHL is characteristically progressive, such that only about one-half of those who will eventually develop hearing loss are captured by universal hearing screening at birth. The 2007 American Academy of Pediatrics (AAP) and Joint Committee position statement on infant hearing called for hearing tests and neurodevelopmental assessments until school age.

Perinatal CMV infection can occur intrapartum because CMV may be in the cervix during late pregnancy and transmitted postpartum via human milk. Perinatal disease is mostly asymptomatic but may manifest as transient mild thrombocytopenia or transaminitis at 2 to 8 weeks of age. Among CMV seropositive women, 32% to 96% will excrete CMV into their milk; the peak period of excretion is 3 to 4 weeks after delivery. The risk-benefit ratio of pasteurizing human milk for the prevention of infection is unclear, and it is not recommended to withhold milk produced by CMV-seropositive mothers from healthy term infants.

To diagnose congenital infection, urine or saliva obtained within 14 days of birth is the best sample from which to isolate the virus by culture because of high titers shed from these fluids. Cultures obtained after 10 to 14 days do not differentiate congenital from perinatal acquisition of infection. Polymerase chain reaction (PCR) amplification of viral DNA is rapidly replacing viral culture as the most sensitive and efficient method for the detection of CMV. Real-time PCR assays of both liquid and dried saliva samples have reported sensitivities of 97% and 99.9%, respectively, compared with saliva rapid culture.

For prenatal diagnosis, isolated IgM titers in pregnant women are not sufficient; viral DNA in amniotic fluid together with ultrasound findings such as echogenic bowel and CNS abnormalities with IUGR, are most suggestive. Abnormal prenatal findings on ultrasound are associated with increased risk of sequelae. No guidelines exist for the treatment of CMV during pregnancy; using antepartum CMV hyperimmune globulin requires further assessment.

Treatment of congenital infection remains limited and suboptimal. Therapy of symptomatic disease involving the CNS with intravenous ganciclovir for 6 weeks results in modest improvement in hearing outcomes and developmental delays. Its use is associated with adverse effects, including neutropenia, complications of prolonged central venous catheterization, and the potential for sterility (in animal models). Valganciclovir, the oral prodrug of ganciclovir, is currently being investigated for treatment. A randomized, controlled trial is being performed by the National Institute of Allergy and Infectious Diseases (NIAID) Collaborative Antiviral Study Group (CASG), using SNHL as its primary endpoint.

The Institute of Medicine has classified a CMV vaccine at the highest priority to prevent congenital infections, neurologic damage, and deafness, and to avoid major economic costs. Assessing the risk-benefit ratio of universal screening of all infants has significant obstacles including the lack of a standardized, high-throughput screening test and a protocol for follow-up of CMV-infected children. The substantial disparities in CMV risk among seronegative women suggest that prevention strategies should include an emphasis on reaching racial or ethnic minorities and women of low socioeconomic status. Increasing awareness of CMV's public health importance will foster the development of vaccines and drive the industry and regulatory agencies. Education of women and health care professionals about modes of transmission is key for prevention. Avoid kissing toddlers on their mouths, sharing utensils, and lapses in effective hand-washing practices, especially after changing diapers and handling toys.

### **Toxoplasma gondii**

Congenital toxoplasmosis is estimated at 10 to 40 per 100,000 live births, resulting in a large economic burden caused by mental and visual disabilities. Although congenital toxoplasmosis is not a nationally reportable disease, it is potentially preventable through education, screening of mother or newborn, and treatment of the pregnant woman. The implementation of screening interventions has been debated mainly because of differences in seroprevalence rates in different geographic areas and the unknown true burden of disease. The estimated seroprevalence rate in women of childbearing age in the United States is 15%. *Toxoplasma gondii* exposure is attributed to either consuming contaminated pork meat (the microorganism is destroyed by heating) or ingesting oocysts passed in the feces of cats in warm, moist climates. A risk of transmission exists with primary infection across the placenta, but not if infection is acquired before conception. The transmission rate is higher late in gestation (50%–80% vs <10% early in gestation), but anomalies are most severe (50%–80%)

if infection is acquired at 10 to 24 weeks' gestation. Treatment during pregnancy has been shown to reduce the rate of transmission, and seems to reduce serious neurological sequelae in the infant.

Congenital infection may result in fetal loss, be asymptomatic at birth (75%), manifest with symptomatic disease in the neonate within the first few months of life, or present later in life with relapse of undiagnosed infection, most commonly as retinochoroiditis. If untreated, up to 85% of all infected infants (including asymptomatic) will develop visual and learning disabilities with or without seizures later in life. Symptomatic newborns may have 1 or more of the following, which overlap with symptoms of other congenital infections: chorioretinitis, hydrocephalus, and intracranial calcifications (the classic triad of congenital toxoplasmosis); prematurity; cytopenias; jaundice; and maculopapular rash. Markedly increased cerebrospinal fluid (CSF) protein concentration that results from autolysis of necrotic brain tissue is a hallmark of congenital toxoplasmosis. A database on congenital toxoplasmosis in the United States has been accumulated through the National Collaborative Chicago-based Congenital Toxoplasmosis Study (NCCCTS), in collaboration with the Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL). Taking into account potential referral bias from 1991 to 2005 in 164 confirmed infected infants whose mothers had not been treated during gestation, severe clinical manifestations were reported in 84% and included eye disease (92%), brain calcifications (79%), and hydrocephalus (67%). In 61% of the infants, the triad occurred concurrently. The prevalence of clinical signs at birth might also vary among geographic areas of the world depending on the strain of the infecting parasite.

Serology remains the mainstay of diagnosis of infection in the neonate. Commercial kits, with specificity of 80% for detecting IgM, are used and thus should be interpreted with caution and confirmed, preferably in the reference PAMF-TSL. Testing for IgM and IgA antibodies increases the sensitivity to 93% compared with testing for IgM or IgA individually. Infections acquired late in the third trimester of pregnancy may be missed because antibodies have not yet been formed. The presence of IgM antibodies can also be detected in CSF. In addition, CSF, blood, urine, and placenta can be sent for detection of the organism by PCR. Prenatal diagnosis is made based on ultrasound findings and amniocentesis between 17 and 21 weeks' gestation for PCR testing in the presence of IgM, increased IgG, or both.

Affected children who receive treatment have favorable outcomes. Treatment of infants without substantial neurologic disease at birth with pyrimethamine and sulfadiazine for 1 year results in normal cognitive, neurologic, and auditory outcomes, while treatment of infants who have moderate or severe neurologic disease at birth leads to normal neurologic and/or cognitive outcomes for most of the patients, and normal auditory function in all.

Systematic serologic screening of either the newborn or the mother should be considered, given that improved outcomes result when infants receive proper therapy. In countries such as France, where seroprevalence rates are higher than those in the United States, prenatal screening has proven cost effective.

Massachusetts, New Hampshire, and Minnesota perform newborn screening and reporting of toxoplasmosis. Until consensus is reached, raising awareness and educating health care professionals and their patients (eg, using hot water to wash utensils after handling raw or undercooked meat, using gloves during gardening) are imperative to decrease the burden of disease.

### Rubella Virus

Although universal screening and vaccination programs have made congenital rubella syndrome (CRS) a rare occurrence in developed countries, susceptibility rates in women of childbearing age in Southern Asia, Africa, and some parts of Latin America are 20%. The national objective of elimination of rubella and CRS by 2010 from the United States has been attained. Zero to 6 cases are reported per year, most born to foreign-born mothers. Classically, rubella affects the heart, eyes, and ears because virus replication leads to tissue necrosis and damage to endothelium, but thrombotic thrombocytopenic purpura, osteitis (areas of translucency in metaphysis of long bones), and meningoencephalitis may occur in 25% of affected infants. Manifestations can be delayed in the form of purpuric rash, persistent diarrhea, pneumonia, and diabetes. Thus, similarly to congenital CMV, CRS is not a static disease, given the spectrum of time of onset of symptoms. Infants with rubella secrete virus in high titers in their urine for up to 2 years.

### Syphilis (*Treponema pallidum*)

Congenital syphilis is a preventable disease. The seroprevalence rate of syphilis in the United States is 4.5%, but is disproportionately higher in large urban areas, the rural southern states, and the black population (eightfold). Access to adequate prenatal care results in the relatively low national number of about 10 cases of congenital syphilis per 100,000 live births, with a case fatality rate (stillbirths and deaths) of 6.4%. Worldwide, however, congenital syphilis remains a major problem that affects 1 to 2 million pregnancies yearly, and is the second most common cause of stillbirth. Seroprevalence rates in some African countries, where resources for screening and treatment are most needed, exceed 15%. A World Health Organization initiative to eliminate mother-to-child transmission of syphilis aims for 90% or more of pregnant women to be tested for syphilis and 90% or more to receive treatment by 2015.

Prenatal screening is cost beneficial and cost effective. In 2004, the US Preventive Services Task Force strongly recommended that physicians screen all pregnant women for syphilis infection, and new evidence supports the effectiveness of such screening. Ideally, all women should be screened with nontreponemal serologic titers (Venereal Disease Research Laboratory [VDRL] or rapid plasma reagin [RPR] test) during the first trimester, then early in the third trimester and again at delivery for high-risk women (HIV-infected women, those who abuse drugs, those who reside in high-prevalence areas). Testing of women of unknown serostatus at delivery is necessary to identify potentially infected infants. Providers miss well-defined opportunities to prevent congenital syphilis for most cases in the United States.

The various manifestations of congenital syphilis depend on the stage and adequacy of treatment of

maternal syphilis and the gestation and immunologic response of the fetus. Transmission can occur any time during pregnancy, and intense inflammatory responses and prostaglandins induced by disseminated fetal infection may be responsible for fetal death, preterm delivery, and severe growth restriction. Congenital syphilis is more likely to occur with maternal primary and secondary syphilis (60%–100%), if maternal disease is of unknown duration or untreated, if fewer than 4 weeks have elapsed between therapy and delivery, and if maternal plasma nontreponemal titer (VDRL or RPR) is more than 1:16 after therapy or at delivery. A potentially higher rate of treatment failure exists in HIV-positive pregnant women.

Evaluation for congenital syphilis is warranted if the infant's nontreponemal titer (noncord blood) is 4-fold higher than the mother's or if the mother's titer has increased 4-fold; nevertheless, any increase in the infant's titer should be considered for evaluation. Using the same nontreponemal tests for the mother-infant pair is imperative. Treponemal tests (FT-ABS, MHA-TP, TP-PA) are not useful for the infant. Signs of congenital syphilis are nonspecific and include prematurity and low birth weight (10%–40%); hepatomegaly, with or without splenomegaly (33%–100%); a blistering, scaly, copper-colored skin rash (40%); periostitis and osteochondritis (75%–100% vs 20% in asymptomatic infants); pseudoparalysis (12%); respiratory distress (35%); CNS involvement with high CSF protein and pleocytosis (25% vs 10% in asymptomatic infants); Coombs-negative hemolytic anemia with hydrops; and thrombocytopenia and fever (10%–45%). Although more than one-half of affected infants are asymptomatic at birth, lumbar puncture and long-bone radiographs are often justified because 60% of these infants may be infected and develop disease at 4 to 8 weeks of life manifesting as snuffles, hepatosplenomegaly, lymphadenopathy, rash, or osteochondritis; or the disease may develop much later in life. Treatment of confirmed or highly probable congenital syphilis is with penicillin (intravenous or intramuscular) for 10 days; ampicillin is not acceptable. Follow-up with serologic assays should be carried out for at least 6 months. In the presence of mucocutaneous skin lesions or nasal discharge, gloves should be worn until 24 hours after initiation of therapy.

### Parvovirus B19

Parvovirus B19 virus is transmitted in utero and has been identified as a cause of adverse fetal and neonatal outcomes. The virus is cytotoxic to erythroid progenitor cells inhibiting erythropoiesis. Seroprevalence rates vary from 50% to as much as 70% in day care educators. Transmission rate during pregnancy is 30%, and although most newborns are asymptomatic and healthy, some evidence suggests that a high rate of intrauterine viral infection occurs throughout gestation and the virus persists until birth and beyond. Adverse outcomes such as fetal anemia, IUGR, neurologic anomalies, and nonimmune hydrops fetalis, as well as fetal death (overall risk 5%), are more likely if infection is acquired in the first half of pregnancy. The virus is not transmitted through breastfeeding. Prenatal diagnosis is made by maternal IgM antibodies and

viral DNA in fetal blood. Detection of B19-specific IgM in infant serum (EIA) is the preferred test postnatally, but sensitivity and specificity vary; viral DNA from serum or tissues can be confirmatory.

## PERINATAL INFECTIONS

### Human Immunodeficiency Virus

Maximal reduction of perinatal HIV infection is among the goals of the Centers for Disease Control and Prevention (CDC) Advancing HIV Prevention Initiative, which was updated in 2013. In order to reach this goal, HIV testing and antiretroviral (ARV) prophylaxis and treatment are essential. The CDC recommends that all states require public health reporting of all cases of perinatal HIV exposure in infants. With maternal diagnosis and prophylaxis during the perinatal period, perinatal HIV transmission is usually preventable in all but 2% or less of cases, adding up to approximately 150 cases in the United States yearly, mostly because of missed prevention opportunities. The AAP recommends routine education and HIV testing, with consent, of all pregnant women in the United States. Third trimester repeat testing should be done if a woman has risk factors, is in an area of high prevalence, or has previously refused. Current guidelines recommend using highly active antiretroviral therapy, preferably a regimen that includes zidovudine, for women whose plasma HIV RNA levels are greater than 1,000 copies/mL. If the mother's status is unknown, testing during labor or immediate testing of the newborn by a rapid HIV antibody test are recommended. In some states, rapid testing is required by law. The infant's primary care physician plays a key role in preventing mother-to-child transmission of HIV by identifying HIV-exposed infants, prescribing ARV prophylaxis for these infants, and promoting avoidance of HIV transmission through human milk. Continued efforts should focus on collecting data to identify the missed opportunities and to modify practices accordingly, sustaining the commitment to reinforce recognized factors such as increased accessibility to prenatal care, enhancing counseling, and lowering barriers such as social stigma and informed consent.

Most transmission of HIV is peripartum (80%), but it can occur in utero, especially in the third trimester, or postpartum via breastfeeding. Newborns are asymptomatic but if untreated will progress to AIDS within a year. The higher the maternal HIV RNA levels, the higher the risk of transmission. The preferred test for diagnosis of HIV infection in infants is HIV nucleic acid detection by PCR assay of DNA extracted from peripheral blood mononuclear cells, not umbilical cord blood. Approximately 93% of infected newborns have detectable HIV DNA by 2 weeks of age. A third PCR should be performed at 1 to 2 months of age. Prophylaxis with zidovudine alone for 6 weeks is indicated for most exposed infants.

### Hepatitis B Virus

Five percent of the US population and 350 million people worldwide are infected with hepatitis B virus (HBV), and 1 million people die each year of HBV-associated disease. HBV is highly endemic in China and Southeast Asia, among other places. Because only

1 serotype of HBV has been found, a protective vaccine has been developed, and routine immunization programs have decreased HBV prevalence. Most states require that all mothers be tested for serologic evidence of HBV infection. Because of its lipoprotein envelope, HBV resists enzymes in the blood. The blood of carriers often contains approximately 100 million infectious particles per milliliter, making it among the most infectious of all viruses: 1  $\mu$ L of blood is sufficient for spread.

Most transmission occurs through the blood of the infected mother mixing with that of her child during childbirth. Without intervention, 70% to 90% of infants will be infected at birth if the mother tests positive for both the hepatitis B surface antigen and the hepatitis B e antigen; the transmission rate drops to 35% if the mother tests negative for the hepatitis B e antigen. Hepatitis B vaccine administered within 12 hours of birth to exposed newborns, together with hepatitis B immune globulin (HBIG), reduce the vertical transmission rate by almost 90%. This combination provides sufficient protection against any further theoretical risk. Ninety percent of infected newborns become chronic carriers because of their immature immune system. Carriers who acquire the virus at birth comprise the largest cohort to spread the virus to others.

### Hepatitis C Virus

Two percent of the US population and 170 million people worldwide are infected with hepatitis C virus (HCV). Similar to HBV, HCV is highly infectious. Unlike HBV, HCV has many serotypes because of its high mutation rate; hence creating a universally effective vaccine has been difficult. Maternal-fetal transmission of HCV likely occurs either in utero or intrapartum, and 7% to 10% of newborns of affected mothers will be infected at birth. The risk of vertical transmission is greatly increased if the mother is coinfecting with HIV unless she is receiving highly active antiretroviral therapy, which eliminates the difference in risk. No current recommendations have been issued to screen mothers for HCV, given the absence of an intervention to prevent vertical transmission. Testing for the presence of anti-HCV antibody is recommended for HIV-positive mothers in addition to those with past or current intravenous drug use, known HCV exposure, and history of blood transfusions before 1992. HCV-infected mothers can breastfeed their infants; HCV transmission rates in milk of HCV antibody-positive but HCV-RNA-negative mothers are reported to be near zero. HCV antibodies in colostrum and mature human milk seem protective for infants born to HCV antibody-positive but HIV-negative mothers. However, as these antibody levels wane, the risk for HCV transmission in human milk has been documented to increase. Because of the 50% chance of viral reactivation (conversion to HCV-RNA-positive status) in HCV antibody-positive women, additional HCV-RNA testing is recommended during breastfeeding.

Infected infants are asymptomatic. They may have transient viremia and maternal anti-HCV antibodies during the first year of life. PCR for HCV can be obtained as early as 1 month of life to confirm infection of the infant. Alternatively, anti-HCV antibody testing should be performed in the infant during the first 12 to 18 months of life.

### Herpes Simplex Virus Types 1 (Mucosal) and 2 (Genital)

Neonates have the highest frequency of visceral and CNS infection of any HSV-infected population of patients. The morbidity and mortality associated with this virus cannot be overemphasized: the untreated case-fatality ratio is 60%. Early detection and treatment are required to reduce neurologic sequelae in surviving infants. A third of the world is infected with HSV. Sixty percent of women of childbearing age are seropositive for HSV-1, and 25% of the US population is seropositive for HSV-2. The seroconversion rate during pregnancy is 1% to 2%. The estimated number of neonatal herpes infections in the United States is 10 to 40 cases per 100,000 live births (~1,500 cases annually), with up to one-quarter of cases caused by HSV-1 infection.

Virus reproduction initiates rapidly in epithelial cells. Subsequently, the virus establishes latency in the surrounding sensory nerve cells. From time to time, reactivation occurs and leads to infection of the surrounding epithelial cells. Perinatal transmission occurs via contact between the virus produced in the epithelial cells and genital secretions (or saliva) of the mother and the baby's abraded skin, which is denuded of keratin, thus exposing epithelial cells during (or after) birth. Approximately 90% of transmission occurs during delivery and less than 10% postnatally. The mother may have primary or recurrent active genital lesions or subclinical virus shedding. Maternal IgG is somewhat protective. With first-episode primary maternal infection and shedding at delivery, an estimated 60% of babies acquire neonatal HSV disease; with first-episode nonprimary maternal infection and shedding at delivery (ie, mother is positive for HSV-1 antibody but she is having her first HSV-2 disease or vice versa), an estimated 25% of babies acquire neonatal HSV disease; and with recurrent maternal infection and shedding at delivery, about 2% of babies acquire neonatal HSV disease. Since disease may be subclinical in the mother, more than 70% of infants with neonatal HSV are born to mothers with no symptoms or signs of HSV lesions at delivery.

In the immune-immature host, the virus can reproduce in high numbers and spread systemically from the eye, skin, and mouth to the CNS, adrenals, liver, and lungs. Liver involvement is marked by fever in the newborn. Disease is most commonly evident by approximately 12 days of life (range, 3–21 days of life). If acquired postnatally, it can occur as late as 28 days. HSV disease manifests in 1 of 3 forms: skin, eye, and mouth (SEM) disease, usually with a vesicular rash, occurring at approximately 7 to 10 days; CNS disease, which presents at approximately 17 days with irritability, lethargy, poor feeding, apnea, and seizures; and disseminated disease, which occurs at 5 to 9 days of life, mimicking sepsis, with fulminant hepatitis, respiratory failure, meningoencephalitis, and mortality rate of 30%. With disseminated disease, the brain is probably infected via blood, whereas in CNS disease, infection is probably the result of neuronal spread. If untreated, 70% of SEM disease progresses to CNS or disseminated disease. The sequelae of CNS disease are less severe with HSV-1 than with HSV-2,

but disseminated disease with either virus carries the same death prognosis.

Skin, conjunctivae, oropharynx, rectum, and urine can be cultured for herpes. Growth in cell culture is fast, generally 48 to 72 hours. Detection of HSV 1 and 2 DNA by PCR from CSF has significantly enhanced the detection of CNS disease. A high index of suspicion should be present in all ill infants in the absence of skin lesions. Viral DNA can be detected in CSF for up to 2 weeks, although with decreasing sensitivity over time. The application of PCR testing to blood specimens seems promising.

Despite therapy with acyclovir, 70% of infants with CNS disease will have various degrees of disabilities; therefore, the physician must make an early diagnosis and promptly intervene, given the potential of timely therapy. CSF PCR is suggested for all babies with CNS disease at the end of therapy because failure to clear viral DNA warrants continuation of therapy. Data are insufficient at the current time to allow the use of serial PCR assays of blood to establish response to or duration of antiviral therapy.

Cesarean delivery in a woman with active genital herpes lesions significantly reduces, but does not eliminate, the risk of infection. In 2013, the AAP reported guidance on the management of asymptomatic neonates born to women with active lesions using both serologic and virologic studies, if available to the physician, to determine the risk of HSV transmission. Infant HSV surface cultures, and blood PCR if available, should be obtained at 24 hours of life. If the mother has history of genital herpes preceding pregnancy, one can evaluate the infant with surface cultures or blood PCR and treat empirically to prevent progression from neonatal infection to disease only if those results are positive with intravenous acyclovir for 10 days. Ten days of preemptive therapy is also recommended if the mother has a documented or assumed first-episode primary or first-episode nonprimary infection regardless of the neonate's evaluation results (Figure 102-1, Figure 102-2). Preterm babies are more vulnerable, and prematurity generally predicts mortality; thus, infants born at less than 37 weeks may benefit from earlier evaluation and treatment.

It has been reported that neonates surviving HSV disease with CNS involvement had improved neurodevelopmental outcomes when they received suppressive therapy with oral acyclovir for 6 months. Most also use suppressive oral acyclovir therapy for recurrent SEM disease that may be associated with CNS involvement in 10% of instances. Neutropenia is a known but reversible adverse effect of such treatment.

### Enteroviruses

Enteroviral infections of the neonate are common. In most cases, infection is acquired from the mother perinatally in the summer months and less often from the hospital via caretakers in close contact with the infant. Coxsackievirus group B serotypes 2 to 5 and echovirus type 11 can cause fulminant, sometimes fatal, disease in the neonate, especially if it occurs early (between 3 and 7 days of age). Early symptoms are poor feeding and respiratory distress; generalized disease mimics sepsis or disseminated herpes infection,

with myocarditis and meningoencephalitis or fulminant hepatitis. More than one-half of patients may die despite adequate supportive therapy. Although neonates respond by mounting an antibody reaction, macrophage function, which is necessary to limit initial enteroviral replication, is not sufficiently mature in the neonate. Premature infants are more susceptible than term infants because of the absence of passively acquired maternal antibody. Diagnosis can be made rapidly by culturing oropharyngeal secretions, feces, or urine, or by detection of viral DNA by PCR from various sites including CSF.

### Chlamydia and Ureaplasma species

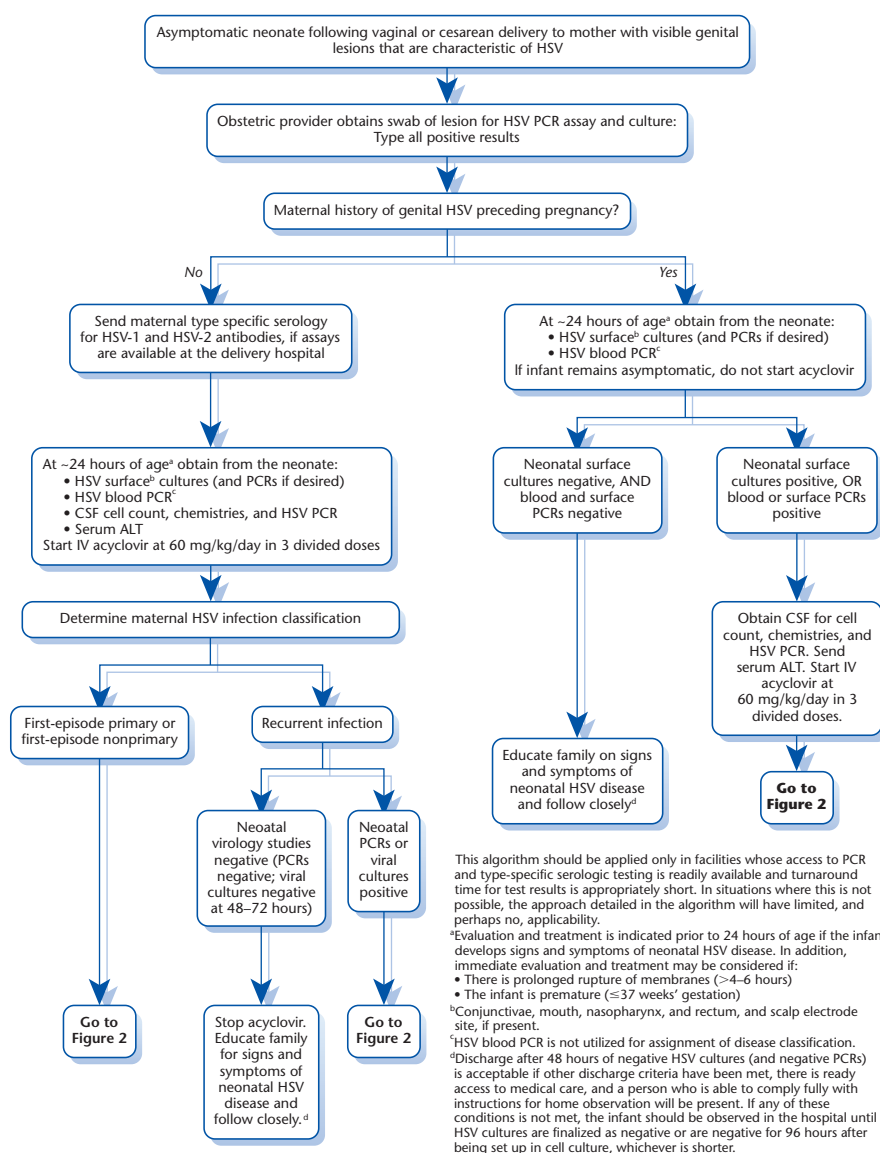

*Chlamydia trachomatis* is the most common cause of sexually transmitted infection, resulting in 100,000 annually exposed neonates in the United States. The infant of an untreated mother has a 35% chance of developing mucopurulent conjunctivitis and a 15% chance of developing pneumonia in the first few months of life.

*Ureaplasma* species can be acquired by the fetus at any time during pregnancy or at birth by passage through an infected birth canal. Several studies have shown that *Ureaplasma* species can cause congenital and neonatal pneumonias, especially in preterm infants; however, controversy remains on whether *Ureaplasma* infection of the respiratory tract contributes to the development of bronchopulmonary dysplasia. The fastidious nature and susceptibility of these organisms to drying mandate careful attention in specimen collection. Isolation from normally sterile sites in an ill infant with otherwise unexplainable causes is suggestive of disease. Antibiotic therapy may be efficacious in such instances.

### Tuberculosis

One-third of the world's population is estimated to be infected with *Mycobacterium tuberculosis*. The mother-to-child transmission rate in resource-limited settings is 15%. Given the increasing number of immigrants to the United States from countries where tuberculosis (TB) is endemic, a high index of suspicion for congenital and perinatal TB must be maintained for ill neonates born to women at risk for TB. Prompt treatment of disease in the mother greatly diminishes the risk of disease in the infant. Congenital TB is rare and is acquired in utero by hematogenous spread or by aspiration or ingestion of infected amniotic fluid. The more common perinatal disease occurs at birth by aspiration of infected amniotic fluid or, more commonly, by airborne transmission from the mother or any adult with TB disease in close contact with the newborn, including health care providers. The incidence of TB disease among foreign-born health care providers in New York State, for example, is 18 per 100,000. Such transmission of *M. tuberculosis* emphasizes the importance of effective latent TB infection testing and prophylaxis programs in health care settings.

Symptoms of congenital TB are nonspecific and include hepatosplenomegaly, respiratory distress with abnormal chest radiograph, fever, and lymphadenopathy, which appear at approximately 2 to 3 weeks of life. Perinatal infection exhibits similarly and, if untreated, often results in local progression

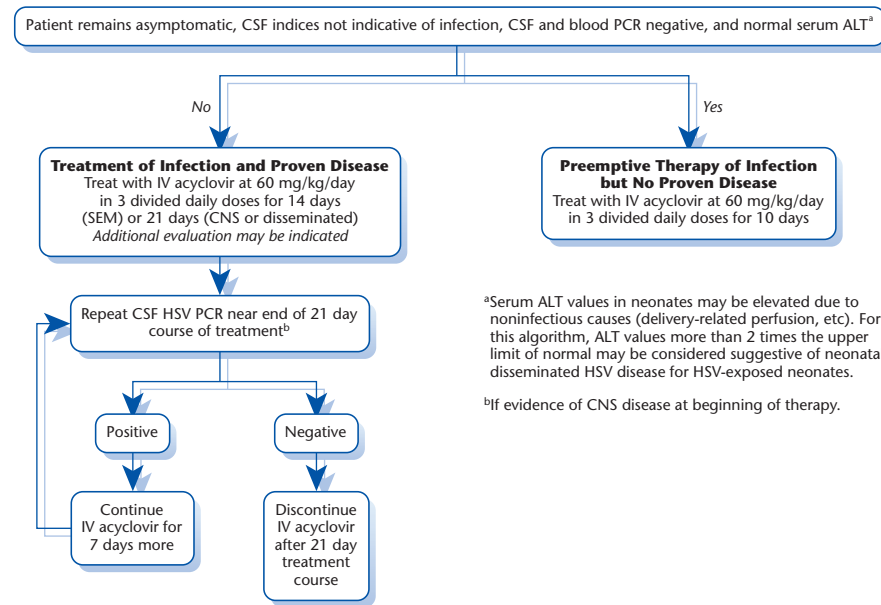

**Figure 102-1** Algorithm for the evaluation of asymptomatic neonates after vaginal or cesarean delivery to women with active genital herpes lesions. ALT, alanineaminotransferase; D/C, discontinue. (Reprinted from Kimberlin DW, Baley J; American Academy of Pediatrics Committee on Infectious Diseases and Committee on Fetus and Newborn. Guidance on management of asymptomatic neonates born to women with active genital herpes lesions. *Pediatrics*. 2013;131[2]:e635–e646.)

and dissemination (miliary TB), including meningitis. Because treatment of the infant with multiple drugs greatly improves outcome, making the correct diagnosis is imperative. Diagnosis is established by demonstrating acid-fast bacilli or isolating *M tuberculosis* from body fluids. The tuberculin skin test (TST) is initially negative and may take 1 to 3 months to become positive. A positive TST result in infants is a sentinel indicator for recent transmission. If the mother (or household member) has received antituberculosis therapy for less than 2 weeks before delivery, then the exposed newborn should be treated with isoniazid for 3 months after active TB disease is excluded. A TST is performed at that time, and therapy is discontinued if negative. Similar recommendations ought to be implemented in exposed infants in the nursery or neonatal intensive care unit (NICU).

Infants suspected of having congenital TB need to be isolated and appropriate infection control precautions undertaken. Because HIV infection represents the greatest risk factor for acquisition of TB, both mother and child should be tested for HIV. Separation of the infant from the mother (or household member) is necessary only if the mother has multidrug-resistant TB (or, inevitably in the future, extensively drug-resistant TB) or if noncompliance is expected.

### Varicella-Zoster Virus

The only herpesvirus that can also be transmitted without person-to-person contact is varicella-zoster virus (VZV). With current vaccination programs in the United States, susceptibility rates of pregnant women are low, and congenital infection with VZV

**Figure 102-2** Algorithm (continued) for the evaluation of asymptomatic neonates after vaginal or cesarean delivery to women with active genital herpes lesions. ALT, alanineaminotransferase; D/C, discontinue. (Reprinted from Kimberlin DW, Baley J; American Academy of Pediatrics Committee on Infectious Diseases and Committee on Fetus and Newborn. Guidance on management of asymptomatic neonates born to women with active genital herpes lesions. *Pediatrics*. 2013;131[2]:e635–e646.)

(nervous system stigmata, malformed extremities), which affects 5% of exposed infants, is extremely rare. Perinatal VZV infection is associated with a high death rate if maternal disease develops within 5 days before or 2 days after delivery. Progressive pneumonitis is characteristic of perinatal disease. Postexposure prophylaxis is available and effective.

## NEONATAL SEPSIS

Most common bacterial pathogens that cause neonatal sepsis are acquired perinatally.

### Group B *Streptococcus*

Group B *Streptococcus* (GBS) was the leading cause of neonatal infections in the 1970s and 1980s, with case fatality rates of 20% to 50%. The implementation of preventive intrapartum antibiotic prophylaxis (IAP) since the 1990s has reduced early-onset disease incidence by 85% to a rate of approximately 25 cases per 100,000 live births, with case fatality rates of 7%, except in preterm infants (<37 weeks' gestation), among whom the fatality rate approaches 25%.

GBS colonizes the genitourinary or gastrointestinal tract (or both) of women. Carriage rates are higher in black women (up to 40% vs 15%). GBS can be transmitted in utero (which may result in stillbirth), at delivery, or postnatally. It is classified as early-onset (before the first week of life with 90% manifesting within 24 hours) or late-onset disease (between 1 week and 90 days of life). The incidence ratio of early-onset to late-onset disease in the era of IAP has dropped from 3:1 to 1:1. In the neonate, early disease manifests with bacteremia, sepsis, pneumonia, and meningitis (<10% of cases). Late-onset disease presents as meningitis (35% of cases), occult bacteremia, and focal infections such as osteomyelitis or arthritis, facial cellulitis,

submandibular cellulitis, or cellulitis-adenitis in other regions. Evaluation for CNS involvement is indicated in the cellulitis-adenitis syndrome.

Since 2002, revised guidelines from the CDC, AAP, and American College of Obstetrics and Gynecology recommend universal rectogenital culture-based screening of pregnant women at 35 to 37 weeks' gestation. Pregnant carriers should receive intravenous penicillin or ampicillin intrapartum (oral antibiotics are ineffective) at least 4 hours before delivery to allow appropriate distribution to amniotic fluid and genital secretions. If GBS status is unknown at the time of delivery, intrapartum antibiotics should be administered in the presence of 1 or more of the following: preterm labor less than 37 weeks, temperature more than 100.4°F (38°C) during labor (as an indicator for maternal chorioamnionitis), rupture of membranes (ROM) 18 or more hours before delivery, previous newborn with GBS disease, or GBS bacteruria during current pregnancy. IAP does not eliminate colonization in women, likely a reason for the unchanged rates of late-onset disease.

Culture remains the gold standard for diagnosis; real-time PCR analysis of samples taken from the ear, nose, or rectum, when standardized, may hasten the speed of diagnosis and avoid unnecessary treatment. Ampicillin and gentamicin are provided empirically for the treatment of GBS disease and substituted with penicillin once the organism is isolated from any sterile site. Duration of treatment for septicemia is 10 days, for meningitis 14 to 21 days.

Guidelines have been put forth for evaluation and management in situations considered high risk for neonatal early-onset sepsis (EOS) such as maternal chorioamnionitis and inadequate IAP. In circumstances where IAP is indicated but not adequately given, the 2010 CDC recommendations advocate for a

limited evaluation (complete blood count [CBC] and blood culture) without empiric antibiotic therapy treatment if the infant is 37 weeks or less gestation with no signs of sepsis, or if ROM is 18 hours or more. In 2012, the AAP Committee on Fetus and Newborn (COFN) published guidelines for EOS evaluation and prevention that advocated clinical observation in this setting for well-seeming infants with a normal physical examination born at 35 weeks' or more gestation. In these infants, a CBC at 6-12 hours without a blood culture is advocated as long as the infant continues to seem well. If the duration of membrane rupture is 18 hours or longer, COFN recommends hospital observation for 48 hours without further testing or cultures.

In 2010, the CDC recommended empiric antibiotics while awaiting limited evaluation results of blood culture and CBC for all infants whose mothers have intrapartum chorioamnionitis. Challenges in the accurate diagnosis of chorioamnionitis (maternal fever is frequently used as a surrogate) and in the use of this obstetric diagnosis to guide neonatal therapy are acknowledged. Recently, there are reports suggesting that the risk of EOS in infants born to women with chorioamnionitis is strongly dependent on gestational age, with risk as low as 0.5% to 1.25% for infants born at more than 35 weeks' gestation. These publications have prompted many centers to develop local adaptations of the recommendations in an effort to avoid unnecessary treatment of uninfected infants. Obstetric and neonatal interventions to prevent EOS are effective and should be continued, with periodic reexamination based on efficacy and cost-effectiveness data.

Healthy-seeming infants without evidence of bacterial infection should not receive broad-spectrum antimicrobial agents for more than 48 to 72 hours, including the well-seeming term infant whose mother was treated for chorioamnionitis and who has a negative blood culture even when the infant's laboratory results (CBC and/or C-reactive protein obtained at 6 to 12 hours of age) are abnormal. Reports based on serial examination, rather than risk factors or screening laboratory tests, are emerging as solid indicators of infection. Adoption of such approaches will require that frequent examinations be performed, particularly over the first 24 hours. Observation may occur at home after 24 hours if the infant is full-term and there is a knowledgeable observer and ready access to medical care.

So far, maternal GBS prophylaxis has not resulted in a greater likelihood of non-GBS infections, such as invasive *Escherichia coli* infections, in newborns except in VLBW infants. Meanwhile, ampicillin resistance has emerged among gram-negative pathogens; thorough evaluation and systematic monitoring for trends in various pathogen prevalence rates and resistance patterns in these infants are critical.

### **Escherichia coli**

*Escherichia coli* (*E coli*), a member of the gram-negative Enterobacteriaceae, which are prevalent in the maternal gastrointestinal and birth tracts, used to be the second-leading cause of neonatal bacteremia, sepsis, and meningitis. In the era of IAP for GBS, the incidence of *E coli* infections in overall neonatal

sepsis has equaled that of GBS. The incidence of *E coli* sepsis has increased in VLBW and premature infants. Transmission risk factors are the same as those for GBS. Many *E coli* strains isolated from neonates express capsular proteins and toxins that facilitate traversing the blood-brain barrier and attaching to brain endothelial cells. Meningitis is more likely when the level of bacteremia is high. The organism can be isolated from sterile sites, and treatment should be adjusted according to the sensitivities. Most *E coli* are ampicillin resistant, and third-generation cephalosporins should be included as empiric treatment of suspected gram-negative sepsis in newborns. Case fatality of *E coli* meningitis is 10% to 20%. CSF should be checked 48 to 72 hours after initiation of antibiotic therapy, and reexamined until sterility. Early head imaging should be utilized to ensure that ventricles communicate, and to assess for other complications such as ventriculitis or abscess. Minimum duration of treatment is 21 days.

Other strains cause epidemic diarrhea in newborn nurseries with listlessness, poor feeding, and watery, mucousy stools developing over 3 to 6 days. Endotoxemia, overgrowth of gram-negative bacilli in the absence of lysozyme (normally present in human milk), and many other factors have been implicated in the pathogenesis of necrotizing enterocolitis. No strategies for preventing gram-negative infections have been identified yet, and because of the diversity of neonatal pathogens, single-pathogen vaccines will have limited effect.

### **Listeria monocytogenes**

*Listeria monocytogenes* is a gram-positive rod that is acquired through ingestion of raw or unpasteurized milk or their products, soft cheeses, undercooked poultry or meat, including patés, or unwashed fruit or vegetables, and can colonize the vagina and rectum of pregnant women. Infection rates have declined in the past decade. It manifests as influenza-like illness 2 to 14 days before delivery in 65% of women, and clinical chorioamnionitis is common.

A nationally notifiable disease, it has characteristics similar to GBS disease. Early-onset sepsis is most likely acquired in utero and has a case fatality rate of about 25%; late-onset (after 1 week of age) meningitis is acquired at parturition and, less commonly, in the hospital environment. Treatment is with ampicillin and gentamicin.

### **Special Considerations for Infants Requiring Prolonged Hospitalization**

Infants in NICUs are at increased risk of developing diseases from several other organisms. Coagulase-negative staphylococci have been the most common cause of hospital-acquired infections in the NICU since the 1980s. *Staphylococcus aureus*, a skin colonizer, is implicated in various clinical entities and outbreaks. Enterococci are isolated in 10% to 15% of neonatal cases of sepsis in the NICU. The emergence of antibiotic resistance will dictate the challenges of therapy in these newborns. Multifaceted interventions that help ensure adherence with evidence-based infection-control practices and the judicious use of antibiotics are essential in controlling these potentially invasive pathogens.

### Candida Species

Invasive *Candida* infections (incidence 1%–15%) have been observed in recent years as a result of the larger numbers of surviving premature, VLBW babies with prolonged central vascular catheter use and prolonged use of broad-spectrum antibiotics. Death (11%–44%) or neurodevelopmental impairment (with and without documented meningitis) occur in young, VLBW infants who develop candidiasis. Other complications include indolent arthritis, osteomyelitis, and endocarditis. *Candida albicans* is the most common and most virulent colonizing species, but it can be treated with fluconazole and is less likely to display resistance during drug exposure. *Candida galbrata* and *Candida parapsilosis* act more as opportunists, but they are capable of developing resistance to azoles under pressure of drug exposure. Some NICUs have adopted prophylaxis with fluconazole to reduce colonization and subsequent invasive fungal infections. Universal prophylaxis with fluconazole may lead to emergence of resistant organisms and increases in the prevalence of non-*albicans* species. No conclusive data exist on changes in late morbidity and mortality rates with this regimen. Targeted short-course fluconazole to VLBW infants who are to receive broad-spectrum antibiotics for more than 3 days has been shown to be cost effective and may alleviate some of the previously mentioned concerns. In addition, newer antifungal agents are being evaluated in this age group.

### Respiratory Syncytial Virus

Premature infants, especially those with chronic lung disease, and certain groups of infants with serious medical conditions (acyanotic CHD requiring medication or surgery in the first year of life, infants with respiratory compromise or severe immunodeficiency), are at increased risk for severe respiratory infections caused by respiratory viruses such as respiratory syncytial virus (RSV) and influenza. Compared with healthy infants, they have prolonged and more severe complications from respiratory infections for the first year of life. Guidelines for prophylaxis against RSV with the monoclonal antibody palivizumab (Synagis) beginning before the onset of RSV season were last revised in 2014. Breakthrough infections occur in 2% to 3% of cases. Early detection with available rapid tests is crucial to optimize supportive care, thus preventing associated morbidity. Vaccinating those around newborns with the influenza vaccine is the only way to protect the infants from infection with influenza viruses.

### Chapter 103

## THE NEWBORN WITH HEMATOLOGIC ABNORMALITIES

M. Catherine Driscoll, MD

Evaluating hematologic disorders in newborns is fundamentally different from evaluating hematologic disorders in older children because the developmental aspects of erythropoiesis and hemostasis are not complete at birth but rather continue throughout much of the first months of life.

### ANEMIA IN THE NEONATE

The fetal and neonatal erythrocyte differs from the adult erythrocyte with regard to life span, membrane structure, hemoglobin (Hb), and metabolic content. The life span of the erythrocyte in a healthy term infant is 60 to 80 days and in a preterm infant is 30 to 50 days.

This time span is significantly shorter than the 120 days of an adult red blood cell. At birth, the erythrocyte reflects the hypoxic environment of fetal life in which oxygen delivery is one-third that of an adult. This relative hypoxia leads to increased erythropoietin and active erythropoiesis evident by increased reticulocytes and nucleated red cells during the first few days of life. At birth, when lungs become the oxygen source, Hb saturation increases to 95%, erythropoietin levels fall, and erythropoiesis significantly decreases.

Hematologic values for the term and preterm newborn reflect the active nature of erythropoiesis in late fetal development during which Hb concentration rises slowly from approximately 14.5 g/dL at 28 weeks' gestation to 15.0 g/dL at 34 weeks to 16.8 g/dL at 40 weeks. The reticulocyte count is elevated for the first 3 days of life and drops to less than 1% by day 7 in the term newborn, whereas in the preterm newborn, the reticulocyte count is higher in cord blood and may remain elevated until day 7 of life.

The physiologic anemia of the term newborn is not a pathologic state but rather an adjustment to the state of excess capability of oxygen delivery relative to tissue needs at birth. The combination of a shortened neonatal red cell survival, decrease in erythropoiesis, and growth-related increase in blood volume leads to a progressive decrease in Hb concentration during the first 2 months of life. This physiologic nadir may occur from weeks 6 to 12 of life, when the Hb concentration is between 9.5 and 11.0 g/dL. Erythropoietin will then increase as sensors in the kidney and liver detect tissue hypoxia, and an increase in reticulocytes heralds an increase in Hb concentration, which rises to a mean of 12.5 g/dL.

Anemia in premature neonates, however, is not physiologic and is multifactorial in nature. Up to 50% of premature infants younger than 32 weeks' gestation will develop symptoms associated with anemia of prematurity. Symptoms may include respiratory difficulties (apnea, periodic breathing, tachypnea), poor feeding and weight gain difficulties, tachycardia, flow murmurs, and pallor. The erythropoietin response to anemia is suboptimal in the preterm infant in whom the liver is the source of erythropoietin and hepatic oxygen sensors may be less sensitive. The preterm infant's shortened red cell survival, expanding blood volume with rapid growth, and iatrogenic blood loss from frequent testing aggravate the effects of erythropoietin deficiency.

Infants weighing less than 1.2 kg will reach their Hb nadir at 4 to 8 weeks with a Hb concentration of 6.5 to 9.0 g/dL. Infants from 1.2 to 2.5 kg will reach a nadir between 5 and 10 weeks with a Hb concentration of 8.0 to 9.0 g/dL. Iron supplementation is recommended for all preterm infants, in the range of 4 to 6 mg/kg/day of elemental iron. Ensuring adequate nutritional intake of vitamin E, B<sub>12</sub>, and folate is also important. Anemia of prematurity typically resolves by 3 to 6 months of age. The Premature Infant in Need of Transfusion randomized clinical trial, published in 2006, demonstrated that transfusion to maintain a high hematocrit does not reduce mortality or

morbidity or improve long-term outcome for infants with anemia of prematurity.

### Approach to Anemia

Three broad classifications of anemia exist in the newborn, including blood loss, hemolysis, and decreased production. The medical history and physical examination may often reveal the cause of the anemia. The maternal history (ABO/Rh, infections, autoimmune disease), obstetrical history (gestation, delivery difficulties), and family history (anemia, jaundice, cholelithiasis, splenomegaly, transfusion history) may identify a cause. The age at presentation is important because a significant anemia detected within the first 24 hours of life is usually caused by blood loss or alloimmune hemolysis. Anemia detected after 24 hours of age points to hemolysis or internal hemorrhage. Anemia detected several weeks after birth may be physiologic or is compatible with Hb disorders or rare hypoplastic erythrocyte disorders. The physical examination of an infant with hemolysis may demonstrate icterus, hepatosplenomegaly, and stigmata of congenital infections. Infants with acute blood loss will exhibit hypovolemic shock, whereas those with chronic blood loss may have pallor without clinical distress or, if there is significant blood loss, may present in congestive heart failure and hydrops. The initial laboratory evaluation of anemia should include a complete blood count CBC, reticulocyte count, evaluation of the peripheral smear, and a direct antiglobulin test (DAT). The diagnosis of anemia should be based on reference ranges for the newborn and must take into account gestational and postnatal age. During the neonatal period, variation in normal hematologic values is higher than at any other time of life.

### Anemia Caused by Blood Loss

Hemorrhage may occur at any time during prenatal, perinatal, or postnatal life. Fetal hemorrhage is more commonly associated with fetal to maternal hemorrhage (FMH), which may occur in up to 8% of all pregnancies. The effects of FMH depend on the volume of hemorrhage and whether it is acute or chronic. Approximately 50 mL of fetal blood must be lost to produce significant anemia in a full-term infant and less for a preterm infant. Infants with chronic blood loss will exhibit pallor and anemia that can be mild normochromic, normocytic (Hb 9–12 g/dL), or hypochromic and microcytic (Hb 5–7 g/dL). Most forms are clinically stable and can be treated conservatively with iron supplementation for 3 months. Symptomatic infants (tachycardia, tachypnea, poor feeding) should be transfused with packed red blood cells. Acute blood loss, however, may result in hypovolemic shock. These infants may have a normal Hb concentration at birth, but anemia will be present hours later as the plasma volume re-expands. FMH may be diagnosed by the presence of fetal RBCs in the maternal circulation. This task can be accomplished by either the Kleihauer-Betke test, which involves examination of a stained maternal blood smear following differential acid elution of Hb A but not fetal Hb, or by flow cytometry techniques. These studies, however, may have negative results if ABO incompatibility exists between

mother and infant in which incompatible fetal red cells may be rapidly removed. Twin-to-twin transfusion (TTTS) may occur in monozygous twins and can result in significant anemia for 1 twin and polycythemia for the other. TTTS has a high rate of fetal mortality (approximately 63%). Hemorrhage occurs because of vascular anastomoses in monochorionic placentas, which allow transfer of blood from 1 twin to the other. Historically the diagnosis was made when there was a weight discordance of 15% to 20% and a hemoglobin difference of more than 5 g/dL between twins. However, because weight or hemoglobin differences are common in monochorionic twins, this definition has been abandoned. Ultrasound now can detect differences in amniotic fluid volume between twins when the donor twin has oligohydramnios and the recipient twin has polyhydramnios. Blood volume discrepancies can also be diagnosed prenatally by Doppler ultrasound velocities of the middle cerebral arteries when the donor twin has higher velocities.

Perinatal hemorrhage is associated with obstetric complications such as placenta previa, abruptio placenta, ruptured umbilical cord, and emergency cesarean section. Placenta previa occurs more commonly in women with a history of previous cesarean birth and increased parity. The incidence is approximately 1 in 3,000 deliveries, and the mortality is high in cases undetected before delivery (33%–100%). Placental abruption occurs when the placenta separates from the uterus. The incidence is 3 to 6 per 1,000 live births and increases with lower gestational age. Mortality is high, with death in 15% to 20% of cases with significant abruption (involvement of more than 50% of the placental surface). Cord rupture can occur from traction on a shortened or abnormal umbilical cord. Cord aneurysms, varices, and cysts can lead to a weakened cord.

Postnatal blood loss is commonly caused by fetal transfusion into the placenta at birth and by birth trauma. Fetoplacental hemorrhage occurs when the infant is held above the placenta at birth. Birth trauma can result in internal hemorrhage. Cephalohematoma and subgaleal hematomas can occur with vacuum- or forceps-assisted births. This diagnosis should be considered when a fluid collection occurs in dependent areas of the infant's head with signs of hypovolemia. Occult hemorrhages usually occur after 24 hours of life. Breech deliveries and infants with macrosomia may develop splenic, renal, or adrenal hemorrhage into the retroperitoneal space as a consequence of a difficult delivery.

### Hemolytic Anemia

Red cell hemolysis is a common cause of anemia in the newborn and has multiple causes. The neonatal red cell has intrinsic properties that lead to shortened survival. The normal neonatal erythrocyte has a less deformable membrane in the microcirculation and is more likely to be sequestered and removed by the reticuloendothelial system. Infants with mild hemolysis may have a blunted erythropoietic response and may not respond with reticulocytosis because of the excess oxygen-carrying capacity of blood. Thus hyperbilirubinemia may be the only symptom in mild anemia.

Severe hemolytic anemia will also be accompanied by an elevated reticulocyte count. Hemolytic anemias can be classified based on immune-mediated disorders, acquired disorders, and hereditary disorders of the erythrocyte.

### Alloimmune Hemolysis

Alloimmune hemolytic anemia, caused by maternal fetal blood group incompatibility (Rh[D] and ABO) is the most common cause of neonatal hemolytic anemia worldwide. The spectrum of alloimmune hemolysis can range from mild anemia and hyperbilirubinemia to severe anemia with hydrops fetalis. Antigens in the ABO, Rh, Kell, MN, Duffy, and Vel systems are expressed on the fetal red cell during the first trimester. The advent of immunoprophylaxis to prevent Rh(D) sensitization in 1968 dramatically decreased the incidence of alloimmune hemolysis. Nevertheless, Rh incompatibility is still a main cause of serious alloimmunization, although ABO incompatibility is far more prevalent. Cases of alloimmunization are detected by a positive DAT, which detects the presence of antibody on fetal red cells or in the plasma (indirect antiglobulin test). Eliminating alloimmunization as a cause of hemolytic anemia is important before testing for other etiologies.

**RH(D) HEMOLYTIC DISEASE.** Rh(D) hemolytic disease occurs in an Rh-negative mother and Rh-positive fetus when fetal red cells leak into the maternal circulation and sensitize the mother to the D antigen on the fetal red cell. The mother produces anti-D immunoglobulin G (IgG) antibody, which crosses into the fetal circulation, causing fetal red cell destruction. First pregnancies usually result in maternal sensitization without significant fetal hemolysis. However, subsequent pregnancies are more severely affected. A first pregnancy with significant neonatal Rh hemolytic disease usually indicates that the mother was previously exposed to Rh-positive red cells, through therapeutic abortion, ectopic pregnancy, or blood transfusion. Approximately 50% of Rh-sensitized pregnancies result in a newborn who requires transfusion postnatally; 9% of sensitized fetuses require intrauterine transfusion, and fetal death occurs in 1.5% of affected pregnancies. Concomitant ABO incompatibility decreases the risk for developing Rh alloimmune hemolysis. Rh-negative women who are not sensitized should receive Rh immune globulin at 28 weeks' gestation and then an additional dose at the birth of an Rh-positive infant. Infants with Rh incompatibility can develop a "late" anemia from ages 1 to 3 months, because of decreased endogenous erythropoietin production. The incidence of late anemia is higher in infants receiving intrauterine transfusions.

**ABO INCOMPATIBILITY.** Alloimmune hemolysis associated with ABO incompatibility occurs in group O mothers and infants with blood group A or B. ABO incompatibility occurs in 12% of pregnancies, but fewer than 1% are associated with significant hemolysis. First pregnancies can be affected, given that naturally occurring maternal anti-A IgG and anti-B IgG cross the placenta. The mild hemolysis of ABO incompatibility is, in part, related to the presence of A and B antigens on other tissues besides red cells.

Therefore other tissues aside from erythrocytes absorb the anti-A IgG and anti-B IgG that cross the placenta. The result of a DAT may be negative because of fewer type-specific antigens on the surface of the fetal red cell compared with adult red cells. The indirect antiglobulin test, however, is usually positive. The peripheral blood smear will show spherocytes, which are the result of reduced red cell surface area caused by the removal of antibody and membrane complexes by the reticulo-endothelial macrophages. Although hemolysis in ABO incompatibility is mild, infants with evidence of hemolysis need to be monitored in the first few days of life for hyperbilirubinemia and for anemia during their first 2 to 3 weeks of life.

**MINOR BLOOD GROUP INCOMPATIBILITY.** The prevalence of other blood group incompatibilities is increasing because of the successful prevention of Rh immune disease. Common incompatibilities occur with Rh (c and E), Kell, Duffy, and Kidd antigens. Kell incompatibilities can result in significant hemolysis and currently account for 22% of alloimmunization cases, surpassing anti-D, which occurs in 18.4% of cases. Because the Kell antigen is expressed on red blood cell precursors, the reticulocyte and nucleated red blood cell numbers in Kell antigen incompatibility is usually not as elevated as with Rh incompatibility.

### Acquired Hemolysis (Nonimmune)

**INFECTION.** Congenital infections (cytomegalovirus, toxoplasmosis, rubella, syphilis) may cause hemolysis, impaired erythropoiesis, and thrombocytopenia. Hepatosplenomegaly is usually present, and an active reticuloendothelial system may account for red cell sequestration. Bacterial infections (group B streptococcus, *Escherichia coli*) may also cause hemolysis, disseminated intravascular coagulation (DIC), and hemorrhage. Malaria should also be anticipated in endemic areas and in individuals traveling from these areas.

**MICROANGIOPATHIC HEMOLYSIS.** Hemolysis may occur when red cells interact with fibrin deposition in the microcirculation. The red cells are sheared and form fragments (schistocytes), which lose their deformability and hemolyze. The most common cause of microangiopathic hemolysis is DIC, which is most commonly associated with infection. Other causes of microangiopathic anemia include cavernous hemangiomas, arteriovenous malformations, renal artery stenosis or thrombosis, severe valvular stenosis, and coarctation of the aorta.

### Hereditary Hemolytic Anemia

Hereditary disorders of erythrocytes may cause hemolysis during the neonatal period. These disorders include membrane defects, enzyme deficiencies, and hemoglobinopathies.

**MEMBRANE DEFECTS.** Hereditary spherocytosis is an autosomal disease caused by mutations in genes for the membrane cytoskeleton proteins ( $\alpha$ - or  $\beta$ -spectrin, ankyrin, band 3). These proteins are important in vertical interactions that tie the membrane cytoskeleton to the lipid bilayer. Spherocytes present on a peripheral blood smear are characteristic of the disease. Spherocytes develop when loss of membrane

surface area occurs caused by microvesiculation of the lipid bilayer. The spherocyte loses flexibility and is entrapped in the microcirculation of the reticulo-endothelial system. Clinical variation is significant. Some patients are transfusion dependent, whereas others have reticulocytosis without anemia. Neonatal hemolysis or hyperbilirubinemia occurs in approximately one-half of patients. A family history will be present in approximately 75% of patients, reflecting autosomal dominant inheritance. Another 25% of patients with spherocytosis have no family history, and the disease may be the result of recessive inheritance or a new mutation. Given that spherocytes are prominent in ABO incompatibility as well, hereditary spherocytosis must be distinguished from ABO incompatibility.

Hereditary elliptocytosis is an autosomal dominant disorder of the membrane proteins, commonly  $\alpha$ - or  $\beta$ -spectrin or less often protein 4.1 or glycophorin C. The disease is clinically heterogeneous, and patients who are heterozygous have elliptical erythrocytes on peripheral smear but are not anemic. A transient hemolysis and poikilocytosis may occur in the newborn period in the heterozygous infant. However, patients who are homozygous or compound heterozygotes may have chronic hemolysis and splenomegaly. Hereditary pyropoikilocytosis is the severest variant and exhibits in the neonatal period with hemolysis that persists. The smear morphologic assay reveals spherocytes, poikilocytes, fragmented red cells, and an extreme microcytosis. The inheritance may be recessive with both parents asymptomatic, or it may be that one parent has hereditary elliptocytosis and the other is a silent carrier.

**ENZYME DISORDERS.** Red cell enzymopathies, with the exception of glucose-6-phosphate dehydrogenase (G6PD) deficiency, are rare. They can occur in the neonatal period with hemolytic anemia and hyperbilirubinemia. G6PD is an X-linked disorder affecting millions throughout the world, primarily in areas endemic for malaria. Hemolysis is, for the most part, episodic and occurs after exposure to infections or potent oxidants. G6PD is an enzyme of the hexose monophosphate shunt that is required to generate the antioxidant glutathione. The absence of glutathione leads to oxidant damage to the erythrocyte with denaturation of globin, which, in turn, damages the red cell membrane and results in red cell hemolysis. G6PD deficiency's clinical heterogeneity is dependent on race and gender. The G6PD A-minus variant results in decreased stability and occurs in individuals of African origin. Reticulocytes have normal enzyme activity; therefore affected patients with an elevated reticulocyte count may be misclassified as having normal G6PD activity. The disease is usually mild with a transient hemolysis primarily seen with infection. The Mediterranean and Asian variant, however, results in more severe hemolysis that may be fatal, especially on exposure to fava beans. The diagnosis is suggested by a nonimmune hemolytic anemia in association with infection or administration of oxidant drugs. In the African variant, the enzyme is present in young reticulocytes such that testing after a hemolytic episode, with the presence of elevated reticulocytes, may reveal normal G6PD activity. Neonatal jaundice is

a common presentation, and in parts of the Mediterranean and Southeast Asia, G6PD deficiency is the most common cause of kernicterus. Male infants with unexplained early jaundice and no evidence for ABO or Rh incompatibility should be screened for G6PD deficiency. Females may also have G6PD deficiency resulting from extreme X-chromosome inactivation in the heterozygote state, or alternatively may be homozygotes for the G6PD gene mutation.

**HEMOGLOBINOPATHIES.** Hemoglobins are developmentally regulated throughout gestation and do not complete the switch to adult Hb A until the first year of life. Hemoglobin consists of 2  $\alpha$ -like and 2  $\beta$ -like globin chains. The  $\alpha$ -like chains consist of  $\zeta$ -globin chains in embryonic life with a transition to adult  $\alpha$  chains by the end of the first trimester. The  $\beta$ -like chains consist of the embryonic  $\epsilon$  globin, which switches to the fetal  $\gamma$  globin in the first trimester. The switch from fetal  $\gamma$  chains to adult  $\beta$  chains starts in the first trimester and is completed during the first year of life. Thus  $\alpha$ - and  $\gamma$ -globin chains are vital to fetal Hb ( $\alpha_2\gamma_2$ ) production, which is the major Hb throughout fetal life. Mutations in the genes encoding  $\alpha$  and  $\gamma$  globins are the cause of Hb disorders that occur in the neonatal period. (See also Chapter 262, Hemoglobinopathies and Sickle Cell Disease.)

**THALASSEMIA.**  $\alpha$ -Thalassemia is a major cause of neonatal hemolytic anemia, hyperbilirubinemia, and hydrops fetalis in Southeast Asia. It is common in areas of the world where malaria is endemic. The molecular basis of  $\alpha$ -thalassemia is deletion of 1 or more of the 4  $\alpha$ -globin genes. Nondeletional forms of  $\alpha$ -thalassemia are known but are less common. Deletion mutants are classified as (1) silent carrier, in which 1 of the 4 genes is deleted or nonfunctional, and there are no clinical or hematologic sequelae; (2)  $\alpha$ -thalassemia trait, in which deletion or nonfunction (in *cis* or *trans*) of 2  $\alpha$  genes results in microcytosis without anemia; (3) Hb H disease (deletion or nonfunction of 3 of the 4 genes), which results in a chronic hemolytic anemia with microcytosis; and (4) homozygous  $\alpha$ -thalassemia (deletion of all 4  $\alpha$  genes), which results in fetal hydrops with severe anemia, hepatosplenomegaly, and usually fetal demise.  $\alpha$ -Thalassemia should be thought to exist in any infant with elevation of Hb Bart syndrome ( $\gamma_4$ ). Infants with the silent carrier or trait status are not symptomatic. Infants with Hb H disease, however, may have neonatal hemolytic anemia and hyperbilirubinemia when exposed to oxidant drugs or infections. Both Hb H and homozygous  $\alpha$ -thalassemia occur almost exclusively in infants of Asian descent who have *cis* gene deletions. Testing the parents of a child with Asian ancestry who has  $\alpha$ -thalassemia trait or Hb H disease is important because future pregnancies might be at risk for a fetus with homozygous  $\alpha$ -thalassemia.

$\beta$ -Thalassemia is common in Southeast Asia, Africa, the Mediterranean, and India. It is caused by point mutations or deletions of the adult  $\beta$ -globin gene, which, in the homozygous state, results in transfusion dependency.  $\beta$ -Thalassemia may be classified as  $\beta^0$  with no production of  $\beta$  globin or  $\beta^+$ , which results in decreased synthesis of normal  $\beta$ -globin protein. Neonates with homozygous  $\beta$ -thalassemia are not symptomatic at birth because fetal Hb ( $\alpha_2\gamma_2$ ) predominates during fetal

and neonatal life. However, by 3 months of age, the switch from fetal to adult  $\beta$  globin chain production is approximately 80% complete, and symptoms of anemia and hepatosplenomegaly will appear.

**HEMOGLOBIN E.** Hb E, common in Southeast Asia, is a structurally abnormal Hb caused by an amino acid substitution of lysine for glutamine at position 26 of the  $\beta$ -globin protein. The Hb E mutation also results in abnormal RNA splicing, which results in decreased synthesis as well, and is considered a thalassemic phenotype. Patients homozygous for Hb E have microcytosis but little or no anemia. Patients who are compound heterozygotes for Hb E and  $\beta^0$  thalassemia, however, are transfusion dependent.

**SICKLE CELL DISEASE.** The sickle hemoglobinopathies are  $\beta$ -globin chain disorders that, similar to  $\beta$ -thalassemia, are asymptomatic at birth. The sickle Hb variants are diagnosed in newborn screening programs by Hb electrophoresis as Hb SS (FS), Hb SC (FSC), Hb S $\beta^0$  thalassemia (FS), and Hb S $\beta^+$  thalassemia (FSA). Alternatively some screening programs use DNA diagnosis. Infants with a sickle hemoglobinopathy are protected during the first months of life by the presence of fetal Hb; therefore few symptoms occur before 6 months of age. (See Chapter 262, Hemoglobinopathies and Sickle Cell Disease, for complete discussion.)

### Hypoplastic Anemia

Hypoproliferative anemias caused by decreased erythrocyte production may occur in thalassemia syndromes, with decreased production of globin chains, blood loss resulting in iron deficiency, congenital infections (parvovirus, rubella, cytomegalovirus), and rare bone marrow failure syndromes. Diamond-Blackfan anemia (DBA) is a rare congenital hypoplastic anemia characterized by the absence of erythroid precursor cells in the bone marrow. The incidence is 2 to 7 per 1 million live births; 10% to 20% are familial, and mutations in 9 genes coding for ribosomal subunit proteins have been identified. Congenital malformations including growth retardation, skeletal anomalies, and renal anomalies are present in approximately 30% of individuals. Approximately 25% of patients will be diagnosed in the neonatal period, when DBA is suggested by a normochromic, macrocytic anemia with a reticulocytopenia. Treatment of DBA includes corticosteroids, which usually produce a remission, but chronic transfusion therapy has also been used. DBA should be distinguished from hypoproliferative anemia caused by maternally acquired parvovirus infection.

## HEMOSTATIC DISORDERS IN THE NEONATE

The diagnosis and management of hemostatic disorders in the newborn is challenging because the system is dynamic and coagulant protein and inhibitor concentrations are age dependent. The hemostatic system in the newborn is thromboprotective, with an overall decrease in thrombin generation. Although the concentrations of hemostatic proteins are related to gestational age, maturation is rapid, and by 6 months of age, adult values are attained in both term and preterm infants. The coagulant proteins that are

vitamin K dependent (FII, FVII, FIX, FX) are approximately 50% of adult levels at birth. The inhibitors of coagulation (antithrombin, heparin cofactor II, protein C, and protein S) are also 50% of adult values at birth. The normal values for prothrombin time (PT) and activated partial thromboplastin time (aPTT) are prolonged in newborns. Platelet counts and life span in the newborn are similar to adult values.

### Approach to the Newborn With Bleeding

Infants with clinically significant bleeding should be evaluated for a hemostatic disorder. Although acquired disorders predominate, hereditary deficiencies of coagulation proteins and inhibitors often present in early infancy. (See Chapter 230, Coagulation Disorders.)

Evaluation of the infant with a bleeding complication should include a medical history that queries familial bleeding problems, maternal illnesses (immune thrombocytopenia, infections), outcomes of previous pregnancies, obstetric problems at delivery, and documentation that vitamin K was given. The physical examination is important in determining whether bleeding is local or diffuse and if the infant has a healthy or sick appearance. Infants with hereditary deficiencies usually display ecchymosis or localized bleeding but seem healthy. However, ill infants with DIC have diffuse bleeding and petechial hemorrhage. Infants with isolated thrombocytopenia usually seem healthy and have petechiae or ecchymoses.

The initial laboratory evaluation should include a PT, aPTT, thrombin time, fibrinogen, and platelet count. Because the hemostatic system in newborns, especially premature infants, is physiologically immature, normal reference values for screening coagulation studies and factor assays will vary from adult normal values. These screening assays will direct selection of other studies, such as specific factor assays. The management of an infant with a hemostatic disorder depends on the defect identified. Replacement therapies may include specific factor concentrates, fresh-frozen plasma, cryoprecipitate, and platelet transfusions.

### Inherited Hemorrhagic Disorders

#### Hemophilia

Deficiencies of coagulation factors VIII and IX are called hemophilia A and hemophilia B, respectively. They are X-linked disorders, and a family history can be obtained in two-thirds of cases, but approximately one-third represent new mutations. The clinical presentation is that of neonatal bleeding in 40% to 70% of cases. The most common sites of bleeding are intracranial hemorrhage, cephalohematoma, umbilical stump bleeding, and circumcision. The aPTT is prolonged for age, and the specific FVIII or FIX factor assay will confirm the diagnosis. The treatment is recombinant factor-specific concentrates. (See Chapter 230, Coagulation Disorders.)

#### Other Hereditary Deficiencies

The most common hereditary coagulation disorder is von Willebrand disease, which occurs in up to 1% of the population. However, symptoms of this disorder do not usually appear in the newborn period because of elevation of von Willebrand factor proteins at birth.

Other, less common severe factor deficiencies (FV, FVII, FX, FXI, fibrinogen, and FXIII) may produce bleeding at birth.

### Acquired Hemorrhagic Disorders

#### Disseminated Intravascular Coagulation

Disseminated intravascular coagulation is a secondary process related to disease states in the neonate such as asphyxia, shock, infection, necrotizing enterocolitis, and respiratory distress syndrome. DIC results from activation of coagulation factors, generation of excess thrombin, and decreased generation of the antithrombotic proteins antithrombin, protein C, and protein S. The consumption of platelets and other coagulation factors leads to diffuse bleeding. DIC occurs in sick infants, and common bleeding manifestations include oozing from mucosal membranes and puncture sites, hematuria, bruising, and intracranial hemorrhage. Laboratory findings may include prolonged PT and aPTT, decreased fibrinogen, increased fibrin degradation products, and decreased platelets. The treatment of DIC involves treating the underlying causes, such as infection, and replacing depleted coagulation and antithrombotic factors with fresh-frozen plasma, cryoprecipitate, and platelets.

#### Vitamin K Deficiency

Infants are at greater risk for bleeding from vitamin K deficiency because of the physiologic decrease in vitamin K-dependent factors (factors II, VII, IX, X) at birth. The 3 clinical presentations of vitamin K deficiency are early, classic, and late.

The early form of vitamin K deficiency occurs in the first 24 hours of life and is linked to maternal medications that interfere with vitamin K stores or function, such as anticonvulsants and antibiotics (including those for tuberculosis). The classic form presents on days 2 to 7 of life in healthy breastfed term infants. This form occurs, in the absence of prophylactic vitamin K, in 0.25% to 1.7% of term infants. The late form manifests between 2 and 8 weeks of life and is primarily caused by disorders that result in malabsorption of vitamin K, such as biliary atresia and other hepatobiliary diseases. Infants thought to have vitamin K deficiency should receive parenteral vitamin K and fresh-frozen plasma for significant bleeding.

#### Liver Disease

The coagulopathies of liver disease in neonates are caused by failure of synthetic function of the liver in combination with a physiologic immaturity of the coagulation system. The common causes of liver disease in the newborn include viral hepatitis, hypoxia, total parenteral nutrition, biliary atresia, and inherited metabolic defects. Coagulopathies related to liver disease must be distinguished from DIC.

## THROMBOEMBOLIC DISEASE IN THE NEONATE

A significant increase has occurred in thromboembolic (TE) disorders in newborns because of improvement in tertiary care and the use of catheters, extracorporeal

membrane oxygenation circuits, and cardiopulmonary bypass, all of which provide thrombogenic surfaces. Approximately 50% of TEs in children occur during the neonatal period; the use of catheters is the major risk factor in 90% of TEs.

### Genetic Risk Factors

Hereditary risk factors for TE rarely contribute to neonatal thrombosis unless a significant acquired risk factor is also present. Testing for prothrombotic genetic risks should be reserved until an infant is at least 3 months of age because of the physiologic decrease in these factors (proteins C and S) at birth. Exceptions, however, would include infants with purpura fulminans, which is often a symptom of the rare homozygous or compound heterozygous state for proteins C and S or antithrombin deficiencies. Besides these antithrombotic proteins, other genetic risks include factor V Leiden, which results in resistance of activated protein C proteolysis of FVa. Factor V Leiden is the most common inherited risk factor and occurs in 5% of whites. Prothrombin gene mutation 20210 is another genetic risk factor and is associated with increase in prothrombin levels.

### Acquired Risks

The use of catheters, central venous lines, and umbilical lines is the most common risk factor for TE in newborns. Clinical signs of TE in central venous lines include loss of patency, limb swelling and discoloration, pulmonary embolism, chylothorax, and superior vena cava syndrome. Umbilical venous and arterial catheters induce clots in 1.7% to 30% of patients; however, most are asymptomatic. Arterial clots can result in ischemia and organ dysfunction and have resulted in limb-length discrepancy. The diagnosis of TE can be made by compression Doppler ultrasound, magnetic resonance venography, and computed tomographic scan. Therapy in newborns is not guided by clinical trials data but may include short-term anticoagulation, conventionally 6 weeks to 3 months of anticoagulation, or close monitoring.

### Renal Vein Thrombosis

Renal vein thrombosis (RVT) is the second most common TE in neonates and accounts for 10% of neonatal venous TE, with approximately one-half occurring in preterm infants. RVT usually causes hematuria, flank mass, and thrombocytopenia, and these are bilateral in approximately 20% of cases. The risk factors for RVT include asphyxia, congenital heart disease, polycythemia, dehydration, sepsis, and infants of diabetic mothers. In a small series, the prevalence of thrombophilia was higher in neonates with RVT. The long-term morbidity includes hypertension and decreased renal function. Use of anticoagulants should be considered for unilateral RVT extending into the inferior vena cava and patients with bilateral RVT.

### Neonatal Stroke

Approximately 25% of arterial ischemic stroke during childhood occurs in the neonatal period, commonly in

term infants. Seizures are the most common clinical presentation; approximately 50% of newborns with a seizure have an arterial infarct as reflected on magnetic resonance imaging. Acquired risk factors for arterial stroke include asphyxia, sepsis, congenital heart disease, dehydration, meningitis, and delivery complications. Outcomes reveal no sequelae in 30% to 50% of patients, and the remaining develop hemiplegia, seizures, cerebral palsy, and visual impairment. Anticoagulation or antiplatelet therapy is usually not recommended, except in cases of a cardioembolic source or recurrent events.

Sinovenous thrombosis (SVT) is less common than arterial stroke but commonly occurs in the newborn period. The major sites for SVT are the superior sagittal and transverse sinuses. The clinical presentation includes seizures, lethargy, and jitteriness. Physical examination may reveal a tense fontanel and dilated scalp veins. Acquired risk factors for SVT include asphyxia, dehydration, and sepsis. The diagnosis is made by magnetic resonance venography and Doppler ultrasound through the anterior fontanel. For neonates with SVT without intracranial hemorrhage, anticoagulation with low-molecular-weight heparin for 6 weeks to 3 months is recommended. For infants with significant hemorrhage, supportive care and monitoring of the thrombosis by neuroimaging and anticoagulation is recommended if thrombus extension is noted. Seventy percent of patients are neurologically normal at 2 years of age.

## PLATELET DISORDERS

### Thrombocytopenia

The platelet count in newborns is similar to levels in healthy adults. A platelet count lower than  $150 \times 10^9/L$  is classified as thrombocytopenia. The prevalence of thrombocytopenia in the healthy newborn is 0.7% to 4%, whereas in the sick newborn, it is 20% to 40%. Causes of thrombocytopenia include diseases associated with decreased production, increased destruction, and a combination of both.

### Decreased Production

Congenital thrombocytopenia is rare and can be seen with bone marrow diseases (amegakaryocytic thrombocytopenia, thrombocytopenia absent radii syndrome, congenital leukemia, metastatic neuroblastoma, osteopetrosis), immune disorders (Wiskott-Aldrich syndrome), neutrophil defects (Chédiak-Higashi syndrome), and giant platelet syndromes (Alport syndrome, Bernard-Soulier syndrome).

### Increased Destruction

The most common mechanism leading to thrombocytopenia is increased destruction. DIC often occurs with bacterial infections. A localized consumption of platelets is seen with asphyxia, RVT, necrotizing enterocolitis, maternal eclampsia, and the vascular lesion kaposiform hemangioendothelioma, which causes the consumptive coagulopathy Kasabach-Merritt syndrome. Immune-mediated mechanisms include both alloimmune and autoimmune and should be considered in otherwise

healthy infants with an isolated severe thrombocytopenia (platelets  $<50 \times 10^9/L$ ).

### Combination

Intrauterine infections (eg, toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex, HIV, parvovirus B19) may have neonatal thrombocytopenia, in addition to other stigmata. The mechanisms are multifactorial and include bone marrow suppression and consumption in the reticuloendothelial tissues.

### Approach to Neonatal Thrombocytopenia

The evaluation of a newborn with thrombocytopenia should include a review of the maternal history for infections, medications, immune disorders, previous affected pregnancies, or a family history of thrombocytopenia. Whether the newborn is sick or healthy is important, given that thrombocytopenia in most healthy newborns is caused by immune disorders. Thrombocytopenia within the first 72 hours of life is usually related to maternal or perinatal events, whereas the presentation after day 3 usually implies bacterial sepsis. The laboratory investigation should include a CBC with examination of the peripheral smear, a coagulation screen, and a platelet count on the mother.

Neonatal alloimmune thrombocytopenia (NAIT) occurs when the mother is sensitized to paternal antigens on the fetal platelet and produces an IgG that crosses the placenta and destroys fetal platelets. The incidence of NAIT is 0.18% of pregnancies. The first pregnancy can be affected because fetal platelets leak into the maternal circulation. The most common alloantigen in the white population is human platelet antigen (HPA)-1A (PLA1), which is the cause of 80% of NAIT. However, the actual risk for developing NAIT is also related to maternal human leukocyte antigen (HLA) type because the risk is 140-fold higher with HLA-D3 alloantigen. The clinical presentation is that of severe thrombocytopenia at birth, with intracranial hemorrhage occurring in 15% to 20% of patients. Therapy consists of transfusion of maternal platelets, if available, or intravenous  $\gamma$ -globulin. Alternatively, random donor platelets may be given. If there is no response to a random platelet transfusion, then HPA-1 or -5 negative platelets, or HPA-4 negative for mothers of Asian descent, may be given. The diagnosis can be confirmed by platelet antigen typing of the parents and maternal antibody testing.

Autoimmune thrombocytopenia in the neonate occurs with maternal autoimmune disorders such as immune thrombocytopenic purpura and is milder than alloimmune disorders. Approximately 15% to 45% of infants with maternal immune thrombocytopenic purpura will have thrombocytopenia. Therapies include intravenous immunoglobulin, steroids, and platelet transfusions.

## NEUTROPHIL DISORDERS IN THE NEONATE

Bacterial and fungal infections are major causes of morbidity and mortality in neonates, especially among very low-birth-weight infants for whom infection

rates are more than 40%. Neutrophil production and some neutrophil functions are immature in neonates. The neutrophil functions of phagocytosis and bactericidal activity are at normal adult levels in newborns. However, migration of neutrophils to chemotactic stimuli is impaired. The neutrophil storage pool is also smaller in neonates than in adults and results in a limited response to infectious challenges. The normal neutrophil count in term infants is 8,000 to 14,000/ $\mu L$ , peaking 12 to 24 hours after birth. By 72 hours, normal levels are 2,000 to 7,500/ $\mu L$ . Very low-birth-weight infants exhibit a wider range of neutrophil values, which may range from 2,000 to 14,000/ $\mu L$  12 hours after birth and fall to 1,000 to 7,500/ $\mu L$  at 48 hours.

### Neutropenia

Neutropenia in the neonate can be caused by increased destruction or decreased production. Increased destruction of neutrophils is most commonly associated with infections and less often with immune-mediated mechanisms such as alloimmune or autoimmune disorders.

*Alloimmune neutropenia* results from maternal transfer of IgG antibody directed against fetal neutrophil antigens. Maternal sensitization may occur at any time during gestation and, similar to alloimmune thrombocytopenia, can occur in the first pregnancy. The incidence is 0.5 to 2 per 1,000 live births. Commonly the neutropenia is detected in the first week of life when the neonate becomes febrile or develops an infection. Typically the neutrophil count is 100 to 200/ $\mu L$ , with otherwise normal values for white blood cell count, hemoglobin, and platelets. The clinical course varies, but most infants have infections of the umbilicus, skin, or respiratory tract. However, more serious infections, such as sepsis and meningitis, may occur. Treatment includes prompt administration of broad-spectrum antibiotics. Intravenous immunoglobulin has not produced consistent results and has a limited role in therapy. Recombinant granulocyte colony-stimulating factor (rG-CSF) has had more success in increasing neutrophil counts. Neutropenia typically has a mean duration of 11 weeks. Diagnosis is made by testing for antineutrophil antibodies in the infant and mother, and neutrophil antigen typing of the infant and both parents. Several neutrophil-specific antibodies have been identified, and the most common are directed against the neutrophil antigens NA1, NA2, NB1, and NC1.

*Autoimmune neutropenia* (AIN) in the neonate is seen when the mother has a diagnosis of AIN with maternal transfer of auto IgG neutrophil antibodies. Symptoms and treatment is similar to infants with alloimmune neutropenia.

Decreased production of neutrophils in neonates can be seen in infants of hypertensive mothers, in twin-to-twin transfusions, and in Rh hemolytic disease. In most cases, neutropenia is transient and may persist for about 5 to 8 days. Other causes of decreased production of neutrophils include rare genetic disorders such as severe congenital

neutropenia (SCN) and Shwachman-Diamond syndrome. SCN is a heterogeneous disease with autosomal dominant, recessive, and X-linked forms characterized by reduction in circulating neutrophils caused by a maturation arrest of bone marrow progenitor cells. Mutations are described in genes for neutrophil elastase (ELA2), granulocyte colony-stimulating factor receptor (CSF3R), HAX1 mitochondrial antiapoptotic protein, and the Wiskott-Aldrich syndrome protein (WASp). Most patients present with life-threatening infections during the first 6 months of life. Absolute blood neutrophil counts are usually less than 200/ $\mu$ L, and daily administration of rG-CSF results in neutrophil counts greater than 1,000/ $\mu$ L, although 10% of patients may be refractory to rG-CSF. There is concern over the use of rG-CSF therapy in patients with the CSF3R mutation because these patients are prone to develop myelodysplastic syndrome and acute myelogenous leukemia. Shwachman-Diamond syndrome is a rare bone marrow failure and cancer predisposition disorder affecting multiple organs. Mutations in the Shwachman-Diamond syndrome gene are found in most patients. Shwachman-Diamond syndrome is characterized by dwarfism, exocrine pancreatic insufficiency, metaphyseal chondrodysplasia, and neutropenia. In the newborn period, symptoms may include diarrhea, failure to thrive, eczema, otitis media, and pneumonia. Neutrophil counts range from 200 to 400/ $\mu$ L, and rG-CSF can increase neutrophil counts to a normal level.

#### Approach to Neutropenia in the Neonate

The evaluation of the newborn with neutropenia should include a thorough history with regard to a familial history of infections and neutropenia. The obstetric history should include queries for peripartum infection, maternal hypertension, medications associated with neutropenia, fetal distress, and asphyxia, especially for infants presenting in the early neonatal period. Infants with persistent neutropenia should be evaluated for alloimmune neutropenia by detection of antineutrophil antibodies in the infant and maternal blood, followed by parental neutrophil antigen typing when appropriate. Patients with negative neutrophil antibodies and persistent neutropenia, with absolute neutrophil count less than 500, should be evaluated for SCN and Shwachman-Diamond syndromes by bone marrow analysis and genetic testing.

### PRENATAL DRUG USE: NEONATAL EFFECTS AND THE DRUG WITHDRAWAL SYNDROME

Enrique M. Ostrea Jr, MD; Neil Joseph B. Alviedo, MD;  
Felix Banadera, MD; Josef Misael Cortez, MD;  
Lilia C. De Jesus, MD

#### INTRODUCTION

Few barriers exist to the passage of most drugs across the placenta or to their biotransformation in the placenta, which can produce inactive or active drug metabolites. Maternal drug use during pregnancy increases the risk of complications such as stillbirths, meconium-stained amniotic fluid, premature rupture of the membranes, maternal hemorrhage (abruptio placenta or placenta previa), and fetal distress. Newborns exposed to drugs in utero experience greater morbidity and mortality compared to other neonates. Problems include a higher incidence of asphyxia, prematurity, low birth weight, infections (including sexually transmitted infectious diseases), pneumonia, congenital malformations, cerebral infarction, drug withdrawal, and acquired immunodeficiency syndrome. Long-term sequelae also have been reported, including delays in physical growth and cognitive development, sudden infant death syndrome, and learning disabilities. This chapter discusses complications of the infant who is antenatally exposed to drugs with emphasis on the neonatal abstinence syndrome.

In 2012, an estimated 23.9 million Americans ages 12 or older were current illicit drug users, meaning they had used an illicit drug during the month prior to the survey interview. This estimate represents 9.2% of the population ages 12 or older. Illicit drugs include marijuana/hashish, cocaine (including crack), heroin, hallucinogens, inhalants, and prescription psychotherapeutics (pain relievers, tranquilizers, stimulants, and sedatives) used nonmedically. Marijuana was the most commonly used illicit drug. Among pregnant women ages 15 to 44, 5.9% were current illicit drug users based on data averaged across 2011 and 2012. This was lower than the rate among women in this age group who were not pregnant (10.7%). The rate of current illicit drug use in the combined 2011–2012 data was 18.3% among pregnant women ages 15 to 17, 9.0% among pregnant women ages 18 to 25, and 3.4% among pregnant women ages 26 to 44. These rates were not significantly different from those in the combined 2009–2010 data. It should be noted that these statistics were obtained exclusively from maternal interviews and therefore may be subject to significant under-reporting of drug use. In one study, an estimate of drug use among pregnant women varied from 0.4% to 27% where drug use was detected by maternal history, urine toxicology, or both. When a more sensitive

method (meconium drug testing) was employed, a prevalence rate of 44% was found in contrast to 11% by maternal self-report.

### **PATHOPHYSIOLOGY**

Two major theories have emerged to explain the phenomenon of drug withdrawal: disuse hypersensitivity and alternative pathways. The theory of disuse hypersensitivity postulates that a drug may depress certain neural systems and render their targets hypersensitive to their usual stimuli, with an increase in binding sites for the drugs. When the depressant drug is removed, the withdrawal syndrome occurs, caused by rebound hypersensitivity of the affected targets. Morphine, for instance, has been shown to inhibit activation of non-adrenergic cells in the brainstem. Thus, chronic morphine exposure results in an increase in the number of brainstem adrenergic binding sites. When morphine is withdrawn, the abstinence syndrome occurs as a consequence of adrenergic hypersensitivity. The theory of alternate pathways states that a drug may depress a primary neural pathway, and as a result alternate pathways, normally of minor activity, become prominent in an attempt to compensate. When the drug is removed, both the primary and alternate pathways remain operative in an additive fashion and cause the withdrawal syndrome.

As tolerance or addiction to drugs develops in the pregnant woman, passive dependence on the drug also develops in her fetus. Withdrawal of the infant

from drugs may occur in utero or soon after birth. (See Box 104-1 for drugs that cause withdrawal.) In utero withdrawal manifests as an increase in fetal movement or activity, an increase in catecholamine levels in the amniotic fluid, or signs of fetal distress, such as meconium staining of the amniotic fluid or abnormal umbilical velocity waveform. It is not safe for the pregnant addict to undergo rapid or self detoxification, because this will lead to withdrawal in her fetus and its concomitant complications.

### **DRUGS ASSOCIATED WITH THE NEONATAL DRUG WITHDRAWAL SYNDROME**

Drug withdrawal in the mother and infant can occur secondary to use of or exposure to narcotics or non-narcotic hypnosedatives (Box 104-1). However, there is a significant difference in the susceptibility to addiction in the infant compared to the mother. Unlike with narcotics, the development of addiction in the mother to nonnarcotic hypnosedatives requires prolonged and continuous use of large doses, usually over months or years, particularly if the drugs are taken orally. On the other hand, addiction in the neonate to nonnarcotic hypnosedatives can occur even if the pregnant woman takes the drug at therapeutic dose during gestation. For instance, maternal use of phenobarbital for epilepsy may not cause addiction in the mother, but can induce passive addiction in her fetus. There are

#### **BOX 104-1 Drugs of Abuse in Pregnant Women**

##### **NARCOTICS OR OPIATES**

- Morphine
- Codeine
- Heroin
- Methadone
- Propoxyphene (Darvon)
- Pentazocine (Talwin)
- Meperidine (Demerol)
- Oxycodone (Percodan, Tylox, Vicodin, Percocet)
- Hydromorphone (Dilaudid)
- Fentanyl (Sublimaze, Actiq, Duragesic, Wildnil, Alfenta, Sufenta)
- Buprenorphine (Buprenex)
- Nalbuphine (Nubain)
- Butorphanol (Stadol)
- Tramadol

##### **NONNARCOTIC HYPNOSEDATIVES**

- Barbiturates
- Nonbarbiturate sedatives and tranquilizers
  - Bromides
  - Chloral hydrate
  - Benzodiazepines (diazepam, chlordiazepoxide, clorazepate, flurazepam, halazepam, prazepam,

clonazepam, lorazepam, quazepam, estazolam, alprazolam, oxazepam, temazepam, midazolam, triazolam)

- Ethchlorvynol (Placidyl)
- Glutethimide (Doriden)
- Alcohol (ethanol)

##### **STIMULANTS**

- Cocaine
- Amphetamines and congeners
- Nicotine
- Phencyclidine (PCP)
- Marijuana
- SSRIs—venlafaxine, sertraline, paroxetine

##### **INHALANT (VOLATILE SUBSTANCE) DRUGS**

- Paint solvents
- Lacquers
- Glues

##### **OTHERS**

- Baclofen
- Valproate

SSRIs, selective serotonin reuptake inhibitors

also some differences in the withdrawal of the infant from narcotics compared to nonnarcotics. The manifestations of withdrawal from nonnarcotics are often more intense and more commonly involve convulsion. Withdrawal from narcotics in the infant is also observed commonly within the first 3 postnatal days because of the short half-life of narcotics, except for methadone. In contrast, withdrawal from nonnarcotics (eg, phenobarbital) may occur 7 to 21 days after birth because of the slow clearance of the drug in the infant. Lastly, unlike narcotic addiction, neonatal addiction to nonnarcotic hypnotosedatives is often induced by the physician who is unaware that the therapeutic dose of the drug given to the mother is already addicting to her fetus.

The mother may also be addicted to any of a large number of central nervous system (CNS) stimulants. These include cocaine, amphetamines and their congeners, indolealkylamines (eg, LSD, psilocybin), phenylethylamines (mescaline, peyote), cannabinoids, inhalants (solvents and aerosols), and phencyclidines. Neonatal withdrawal from some of these drugs has been described, although it is possible that the manifestations regarded as withdrawal are actually toxic effects of the drug on the infant.

### Narcotics

The term “narcotics,” or “opiates,” refers to a family of natural or synthetic drugs that have morphine-like pharmacologic actions. These include morphine, codeine, heroin, methadone, propoxyphene (Darvon), pentazocine (Talwin), nalbuphine (Nubain), buprenorphine (Buprenex), butorphanol (Stadol), meperidine (Demerol), oxycodone (Percodan, Tylox, Vicodin, and Percocet), hydromorphone (Dilaudid), fentanyl (Immovar, Sublimaze), and tramadol. Extended use of narcotics, even in therapeutic doses, can lead to withdrawal in the infant. The use of methadone in pregnant women for the treatment of opiate addiction is also associated with an abstinence syndrome in their infants at birth, and its severity is related to the maternal dose, cord blood level of methadone, and concomitant use of heroin or benzodiazepines. Neonatal withdrawal from methadone is also more severe and prolonged compared to heroin, and seizures are more likely in affected neonates. The birth weight of infants whose mothers are on methadone is comparatively larger compared to those exposed to those heroin. Buprenorphine has been used as a substitute treatment for maternal heroin addiction and can also induce a neonatal withdrawal syndrome that is less prolonged in comparison to methadone, except if buprenorphine is combined with other drugs such as benzodiazepines. The severity of withdrawal from buprenorphine is also related to the maternal dose. The onset of withdrawal from methadone and buprenorphine can be delayed. Thus, prolonged observation is needed in these infants and includes making the mother aware of this possibility if the infant is discharged early.

There has been increasing use of opiates and sedatives in the treatment of infants, especially in the intensive care unit, because of increasing awareness of the adverse effects of pain experienced by neonates.

The drugs commonly used include fentanyl, morphine sulfate, and midazolam. Withdrawal consisting of shorter sleeping time and increased muscle tone has been observed in these infants when the drugs are abruptly discontinued. In one report, severe midazolam and opioid withdrawal resulted in transient myocardial ischemia which resolved once fentanyl and midazolam were reinstituted.

### Nonnarcotic Hypnotosedatives

#### Barbiturates

Although barbiturates have been used in clinical medicine for more than 50 years, their addiction potential was only recognized at a much later time. It may be the frequent association of barbiturate use with alcohol that masked the identification of the addicting potential of barbiturates. This phenomenon may be explained by the property of barbiturates to attenuate the symptoms of alcohol withdrawal.

Barbiturates are classified on the basis of their duration of action as ultrashort, intermediate, and long-acting.

The intermediate-acting barbiturates are abused most often; for example, secobarbital (Seconal), pentobarbital (Nembutal), amobarbital (Amytal) and butabarbital (Butisol). Abuse of the long-acting barbiturates (eg, phenobarbital) is not as common as abuse of the shorter-acting forms. However, phenobarbital is involved most often with nonnarcotic abstinence in the newborn because it has been used for insomnia, as an anticonvulsant, or for sedation in toxemia of pregnancy.

Passive acquisition by the fetus of physical dependence on barbiturates can occur after prolonged intrauterine exposure to the drug. Barbiturates readily cross the placenta and establish high levels in both maternal and cord blood. Relatively high levels of barbiturates have been found in the fetal brain, liver, and adrenals. The manifestations of barbiturate withdrawal in the neonate are similar, regardless of which barbiturate was used by the mother. However, the time of onset of withdrawal may differ. Withdrawal from intermediate-acting barbiturates occurs within a day after birth, and approximately 3 to 7 days after birth in the case of the long-acting barbiturates.

Barbiturates are metabolized principally by the liver, although a significant portion may be excreted unchanged by the kidney. In adults, for instance, up to 30% of the total dose of phenobarbital ingested is excreted in the urine in unchanged form. The half-life in infants of prenatally administered phenobarbital is almost twice that in the adult and varies inversely with the extent of the prenatal exposure to phenobarbital. The prolonged half-life of phenobarbital in the neonate is caused by a lower glomerular filtration rate and a decreased capacity of the neonatal liver to metabolize drugs.

Withdrawal from barbiturates can occur in infants even at therapeutic, nonaddicting maternal doses. Withdrawal from phenobarbital has been reported in an infant born to an epileptic mother receiving phenobarbital at a dose of 60 mg per day. An awareness of the possibility of late-onset withdrawal, especially after exposure to long-acting barbiturates, should alert

the physician to monitor these infants closely during the first 2 weeks of life.

### **Benzodiazepines**

**CHLORDIAZEPOXIDE.** Chlordiazepoxide is a long-acting benzodiazepine often used in the management of anxiety disorders, withdrawal symptoms from alcoholism, and preoperative anxiety. It has low toxicity and is safe for preanesthetic use during labor. There have been no reports of adverse effects with the occasional use of chlordiazepoxide in the second and third trimester. However, there are well-documented case reports of neonatal withdrawal syndrome among infants who were either chronically exposed to chlordiazepoxide in utero or exposed to small amounts intrapartum. In a set of twins born to a mother who used chlordiazepoxide at a dose of 20 mg/24 hr during the second and third trimesters of her pregnancy, withdrawal occurred on the 21st day of life and consisted of severe irritability and coarse tremors.

**LORAZEPAM.** Lorazepam, which has been used for pregnancy-induced hypertension, has also been used often during labor because of its prolonged amnestic action. Lorazepam and its metabolite do not cross the placenta as easily as other benzodiazepines. However, its elimination from the newborn is slow, taking up to 8 days in term babies and even longer in premature infants. Full-term infants whose mothers had received oral lorazepam were noted to have no complication apart from a slight delay in establishing feeding. In contrast, intravenous use of lorazepam for severe hypertension was associated with neonatal withdrawal and significantly low Apgar scores, hypothermia, poor suck, and depressed respiration that required ventilation.

### **Alcohol**

Ethanol has a depressant effect on the CNS. It is rapidly absorbed by diffusion in the mucosa of the stomach (20%) and intestines (80%). The absorption rate is not affected by pregnancy, but blood alcohol levels may be higher in pregnancy. Ethanol is usually cleared from the bloodstream within 1 hour in adults and 2 hours in newborns. Approximately 95% is metabolized by the liver and 5% eliminated by the kidneys and lungs. Ethanol is metabolized to acetaldehyde and then to acetate. Acetaldehyde is more toxic than ethanol itself.

Infants can undergo withdrawal from alcohol, but this often is mistaken for withdrawal from narcotics or other drugs. The withdrawal from ethanol occurs early (within the first 12 hours of life) because of its short half life and may manifest as abdominal distention, opisthotonos, convulsions, tremors, hypertonia, apnea, and cyanosis. Affected infants are irritable, sleep restlessly, and engage in exaggerated mouthing behavior.

### **Stimulants**

#### **Cocaine**

Data from controlled studies show devastating early effects of prenatal cocaine exposure. After controlling for confounders, at 40 weeks' (40<sup>0</sup>/<sub>7</sub>-40<sup>6</sup>/<sub>7</sub> weeks) gestation, cocaine exposure was estimated to be associated with growth deceleration and a decrease of 151 g, 0.71 cm, and 0.43 cm in birth weight, length, and head circumference, respectively. Neurobehavioral

abnormalities, such as tremulousness, irritability, hypertonicity, high-pitched cry, abnormal sleep pattern, and sometimes seizures, have been observed in infants who have been exposed prenatally to cocaine, and are similar to the manifestations of withdrawal from opiates. It is difficult to separate the overlapping effects of cocaine and opiate withdrawal because it is not uncommon for addicts to abuse both drugs. In general, the CNS manifestations in cocaine-exposed infants are significantly milder than those observed in narcotic withdrawal. Abnormalities in cardiorespiratory patterns (increased episodes of apnea, periodic breathing), EEG (bursts of sharp waves and spikes), and neonatal behavior as assessed by the Brazelton score (impairment of orientation, motor, and state regulation) have also been described. These abnormalities may be manifestations of the drug's stimulant effect rather than withdrawal.

### **Marijuana**

Marijuana is the most widely used illicit drug among women of childbearing age in the United States. Tetrahydrocannabinol (THC) is highly bound to the lipoprotein fraction in the blood. THC crosses the placenta within minutes of administration. The concentrations of THC in maternal and fetal sera essentially are identical.

Most studies do not show a significant effect of prenatal marijuana use on fetal growth or weight. There is an equivocal relationship between prenatal marijuana use and neurobehavioral outcome of the offspring. Prenatal marijuana exposure has been associated with increased fine tremors in the infant, accompanied by exaggerated and prolonged startles (both spontaneous and in response to mild stimuli), poorer visual but not auditory stimuli habituation, decreased ability to regulate state, and disrupted sleep patterns. Elevated serum norepinephrine levels have been observed among these infants. Other reports have found no altered neurobehavioral patterns in marijuana-exposed offspring.

### **Nicotine**

Nicotine is the compound considered primarily responsible for the stimulant effects of smoking. It is absorbed readily from the lungs, almost with the same efficiency as intravenous administration, and is distributed rapidly throughout the body. Nicotine is metabolized principally in the liver into its 2 principal metabolites, cotinine and 3' p-hydroxycotinine. These metabolites have been measured in meconium with the highest concentrations found in infants whose mothers were heavy smokers (>2 packs per day). Of interest, equivalent amounts of cotinine were found in meconium of infants whose mothers were passive smokers and those whose mothers who smoked 1 pack per day, which indicates the significant exposure from passive smoking.

Tobacco is used widely by women of childbearing age. About 1 in 6 pregnant women ages 15 to 44 (15.9%) had smoked cigarettes in the past month, based on combined 2011 and 2012 data. Several studies have investigated the effect of cigarette smoking during pregnancy on newborn behavior and later child development. Offspring of mothers who smoked

during pregnancy have been observed to perform less well on the Brazelton Neonatal Behavioral Assessment Score in such items such as habituating to sound or orienting to a voice, compared with offspring of nonsmoking mothers. Other studies indicate poorer performance with head turning and sucking, lower visual alertness, more crying, tremors, and startles, and increased lability of skin color. In a study of 27 nicotine-exposed and 29 unexposed full-term newborn infants, the tobacco-exposed infants were more excitable and hypertonic, required more handling, and showed more stress/abstinence signs, specifically in the CNS and gastrointestinal and visual areas. Dose-response relationships showed higher maternal salivary cotinine values related to more stress/abstinence signs among the tobacco-exposed infants. The findings suggest neurotoxic effects of prenatal tobacco exposure on newborn neurobehavior; the dose-response relationships could indicate neonatal withdrawal from nicotine. A prospective, 2-group parallel study on 17 consecutive newborns of heavy-smoking mothers and 16 newborns of non-smoking, unexposed mothers (controls) showed that Finnegan withdrawal scores were significantly higher in newborns of smokers than in control infants at days 1, 2, and 4. Significant correlations were observed between markers of nicotine exposure and severity of withdrawal scores.

### **Phencyclidine**

Phencyclidine (PCP) was first introduced as a dissociative anesthetic, but its clinical use was discontinued after reports of adverse effects that included agitation, confusion, delirium, and persistent hallucinations. It remains a popular drug of abuse because of its hallucinogenic and sedative effects. Phencyclidine has strong, centrally mediated effects in animals and humans, and influences many different neuronal systems. It inhibits the uptake and increases the release of monoamines in the brain, interacts with cholinergic and serotonergic systems, and antagonizes the neuronal stimulation caused by the excitatory amino acid N-methyl aspartate.

The prevalence of PCP abuse during pregnancy has not been firmly established because most reports are from urban areas and cannot be generalized nationally. In 1983, a study reported that 12% of a random sample of 200 newborns had measurable quantities of PCP in their cord blood.

Early case reports of PCP-exposed newborns showed abnormal neurobehavioral findings in the infants. These included irritability, tremors, hypertonicity, poor attention, bizarre eye movements, staring spells, hypertonic ankle reflexes, and depressed grasp and rooting reflexes. One of the most characteristic features in infants is a sudden and rapid change in level of consciousness, with lethargy alternating with irritability. The behavior of these newborns has been attributed to PCP intoxication, rather than to withdrawal.

### **Amphetamines**

The amphetamines are a group of chemically related sympathomimetic amines that have both CNS stimulant and peripheral actions. There is a strong abuse

potential because of their psychic effects, which include wakefulness, alertness, mood elevation, self-confidence, a reduced sense of fatigue, and often euphoria and elation.

Methamphetamine, the methylated derivative of amphetamine, is prepared through the reduction of ephedrine or pseudoephedrine. The ease of its synthesis, its availability and affordability, and a prolonged “high” have made it an increasingly popular drug of abuse. Ice, the smokable form of methamphetamine, is claimed to produce an intense euphoria.

An infant born to an amphetamine addict manifests with diaphoresis, episodes of agitation alternating with lassitude, miosis, and vomiting. Infants exposed to both cocaine and methamphetamine are described as having abnormal sleep patterns, tremors, poor feeding, hypertonia, sneezing, a high-pitched cry, frantic fist sucking, tachypnea, loose stools, fever, yawning, hyperreflexia, and excoriation of the buttocks because of irritation from the loose stools. A study of 134 mother-infant pairs whose mothers used methamphetamine during pregnancy were compared to 160 unexposed newborns. Exposure to methamphetamine throughout gestation was associated with decreased growth relative to infants exposed only for the first 2 trimesters. The incidence of withdrawal in infants in the methamphetamine group was 49%, but only 4% required pharmacologic treatment for their withdrawal. Bupropion, which is also called amfebutamone, is an amphetamine marketed to assist with smoking withdrawal and has been shown to be associated with a higher than expected frequency of neonatal cardiac malformations in infants born to women who have used the drug during pregnancy.

### **Antidepressants**

Since their introduction in 1988, the selective serotonin reuptake inhibitors (SSRIs) have become the drug class of choice to treat depression and selected other disorders of mood and behavior. Depression during pregnancy is common, with an estimated prevalence of about 7% to 13%. In a multisite study across the United States, the use of antidepressants during pregnancy was shown to have increased from 2% in 1996 to 7.6% in 2004 and 2005. SSRIs were the most commonly used antidepressants during pregnancy, with a prescription frequency of about 5.6%. Drug withdrawal syndrome associated with antidepressants, both tricyclic antidepressants and SSRIs, is well documented in adults. Newborns whose mothers are on tricyclic antidepressants may exhibit manifestations such as irritability, tachycardia, respiratory distress, sweating, and convulsions. Neonatal withdrawal syndrome associated with maternal SSRI use during pregnancy has been reported from the WHO database with a total of 93 cases identified. About 30% of infants exposed to SSRIs during the third trimester of pregnancy had a 3-fold increased risk of neonatal behavioral syndrome. This syndrome includes signs of toxicity or withdrawal from SSRIs. Possible mechanisms of action of neonatal SSRI syndrome can be attributed to cholinergic overdrive or dependence on the serotonin system. Paroxetine and fluoxetine are the most commonly reported SSRIs associated with neonatal SSRI syndrome. Paroxetine has a short half-life and a distinct

affinity to muscarinic receptors, and is a more potent inhibitor of norepinephrine reuptake than sertraline or citalopram. These aspects of paroxetine may render neonates with in utero SSRI exposure susceptible to withdrawal postnatally. Infants with withdrawal signs usually present within 2 days to 1 month with less than 2 weeks' duration in most cases. Withdrawal signs are characterized as alterations in sleep and changes in the gastrointestinal and central nervous systems. Fluoxetine is known to cross the placenta, and elevated drug levels in cord blood among newborns exposed prenatally have also been described. Late-gestation exposure to SSRIs with long half-life such as fluoxetine may be associated with neonatal toxicity syndrome. These infants present within a few hours after birth and clinically manifest with neurobehavioral and respiratory abnormalities. These effects include acrocyanosis, tachypnea, temperature instability, irritability, and hypoglycemia. Treatment of infants with SSRI syndrome includes placing the infant in a quiet environment with avoidance of overstimulation. The use of sedatives is uncommon.

### Inhalant (Volatile Substance) Abuse

Inhalants produce alcohol-like effects described as a "high," resulting in slurred speech, clumsy movements, dizziness, and euphoria. Lightheadedness and hallucinations/delusions can also occur. Inhalants are often the first drugs used by young children. In a survey conducted from 2002 to 2004, an average of 598,000 youths aged 12 to 17 reported each year that they had initiated inhalant use in the 12 months prior to being surveyed.<sup>95</sup> Youths aged 14 or 15 were more likely to be recent inhalant initiates (39.2%) than was the population as a whole (33.9%). The types of inhalants most often mentioned as having been used included glue, shoe polish, or toluene (30.3%); gasoline or lighter fluid (24.9%); nitrous oxide or "whippets" (24.9%); and spray paints (23.4%). Neonatal withdrawal from volatile substances has been described. The principal products abused are paint solvents, lacquer, and glue. Nail polish remover, lighter fluid, deodorant and hair sprays, whipped cream canisters, and cleaning fluids are all widely used inhalant sources. Toluene and other hydrocarbons may be present. A characteristic chemical odor in the neonate or mother is noted that can persist for several days because the lungs are a major route for excretion, and the highly lipophilic substances are excreted slowly. The typical manifestations in the infant include an excessive and high-pitched cry, sleeplessness, tremors, hypertonia, and poor feeding. Metabolic acidosis also has been described. Withdrawal occurs within the first 24 hours of life, and 2 different patterns are observed. The common form is transient and resolves spontaneously or after a single dose of sodium bicarbonate. The other type is more persistent, lasts for 1 to 2 weeks, and requires treatment with repeated doses of sodium bicarbonate or Shohl solution. The cause of the metabolic acidosis is not known, although it may be secondary to the acid load of toluene metabolite or from renal tubular acidosis.

### Other Drugs

Neonatal withdrawal consisting of seizures has been reported in infants born to mothers who have received

the antispasmodic baclofen during pregnancy. Neonatal hypoglycemia and withdrawal manifestations have also been reported with maternal use of valproate for epilepsy.

## ONSET AND DURATION OF NEONATAL DRUG WITHDRAWAL

The onset of withdrawal is common within the first 72 hours after birth, usually within the first 24 to 48 hours. In a few instances the onset may appear soon after birth, if the drug has a short half-life or if the mother already has begun to experience withdrawal while in labor. Withdrawal occurring after the first or second week has been observed with drugs that have a longer half-life, such as phenobarbital. Among narcotics, delayed manifestations of withdrawal, sometimes as late as 6 weeks, have been observed with methadone.

The onset and severity of withdrawal are affected by several factors including affected by a number of factors, among which are the amount of maternal drug use, timing of the last dose before delivery, use of anesthesia or analgesia in the mother during labor, maturity and nutrition of the infant, and metabolism and excretion of the drugs and their metabolites.

Neonatal withdrawal from narcotics can occur within the first 2 days of postnatal life, usually peaks by the third day, and subsides between the fifth and seventh day. On the other hand, withdrawal from methadone can occur after the first week of postnatal life. Manifestations include irritability, tremors, hypertonicity, sneezing, hiccups, and regurgitation. The duration of withdrawal is related to its severity; it is more prolonged in those with severe withdrawal. Infants treated for withdrawal also show a prolonged withdrawal period. Thus, drug treatment may ameliorate the manifestations of withdrawal but prolong its duration. It is important that the mother be made aware that her infant's symptoms of withdrawal may persist for weeks after discharge from the nursery. The uninformed mother also may misinterpret her infant's irritability as hunger and then overfeed, which can lead to diarrhea and vomiting. The mother also should be instructed on how to reduce the infant's discomfort by swaddling and cuddling. She should be reassured that signs of withdrawal will eventually subside. In most instances, the mother who is well informed can successfully cope with the situation. If drugs are used to treat the withdrawal, relapse may occur if treatment is discontinued abruptly. Although withdrawal manifestations diminish in intensity within the first week after birth, they do not disappear completely. The tremors and irritability may persist for as long as 8 to 16 weeks. Withdrawal from barbiturates, diazepam, chlorthalidone, and even methadone may occur weeks later.

## NEONATAL NARCOTIC WITHDRAWAL

The prototype of drug withdrawal in the neonate is withdrawal from narcotics. The manifestations are multisystemic and involve the CNS and respiratory, gastrointestinal, vasomotor, and cutaneous systems. (See Box 104-2.)

**BOX 104-2 Manifestations of Neonatal Abstinence Syndrome****CENTRAL NERVOUS SYSTEM SIGNS**

- Hyperactivity
- Hyperirritability—excess crying, high-pitched outcry
- Increased muscle tone
- Exaggerated reflexes
- Tremors
- Sneezing, hiccups, yawning
- Short, nonquiet sleep
- Fever

**RESPIRATORY SIGNS**

- Tachypnea
- Excess secretions

**GASTROINTESTINAL SIGNS**

- Disorganized, poor sucking
- Vomiting

- Drooling
- Sensitive gag
- Hyperphagia
- Diarrhea
- Abdominal cramps

**VASOMOTOR SIGNS**

- Stuffy nose
- Flushing
- Sweating
- Sudden, circumoral pallor

**CUTANEOUS SIGNS**

- Excoriated buttocks
- Facial scratches
- Pressure point abrasions

**Central Nervous System**

Neurologic signs predominate and appear early. Findings are those of CNS excitability, such as hyperactivity, irritability, tremors, and hypertonicity. Occasionally, fever may accompany these increased neuromuscular activities.

Hyperactivity manifests as nearly incessant movements of the extremities. When the infant is supine and unrestrained, movements assume a jerky, purposeless nature, apparently perpetuated by unchecked proprioceptive stimuli. When placed in the prone position, the infant's motor behavior becomes more organized. There are crawling movements, which may lead to the infant's displacement from the crib, abrasions or friction injuries to the knees and legs, and other motions such as chin lifting, side-to-side head movement, chest elevation, and hand-to-mouth activity. The latter usually quiets the infant, as does the use of pacifiers.

Hyperirritability manifests as an almost incessant shrill, high-pitched crying. The infant's tone is exaggerated, sometimes assuming an opisthotonic position, making the infant hard to hold. Tremors and myoclonic jerks are frequent and sometimes sustained. Unlike seizures, tremors can be abolished by restraint of the tremulous extremity. The reflexes of the infant, such as Moro, traction response, weight bearing, placing, stepping, crawling, and Landau, are exaggerated. The infant's response to sensory stimuli such as sound and light is disproportionately increased.

Electroencephalographic tracings on the addicted neonate may be abnormal and show high frequency dysynchronous activity suggesting CNS irritability. The prevalence of seizures is estimated to be between 5% and 21% in infants manifesting narcotic withdrawal.

In premature infants, neural hyperexcitability is more episodic than in term newborns. The neonates seem restless and overactive for short periods and

then lapse into periods of lethargy and inactivity. Sustained tremors usually are not seen in premature infants until they reach the gestational age when tone is present in the upper and lower extremities. Sweating, which is seen in the full-term infant, is also not observed in preterm infants.

The normal patterns of active and quiet sleep periods are disturbed in the infant experiencing withdrawal, with a significant decrease in sleep from the normal 3 to 4 hours to less than 1 hour. Infants addicted to heroin or methadone also have fewer periods of quiet sleep. Initially, these findings were thought to be related to withdrawal. However, because these abnormal sleep patterns persist beyond the period of withdrawal, they might be the result of the addiction process itself, rather than the general distress secondary to withdrawal, and may be secondary to the direct effects of chronic opiate exposure on the opiate receptors in the brain involved in sleep regulation.

**Cardiorespiratory Signs**

Abnormalities in ventilation have been described in infants withdrawing from narcotics, including longer and increased frequency of apneic episodes and periodic breathing. During withdrawal, these infants also may also exhibit tachypnea with concomitant respiratory alkalosis. In animals, exposure to morphine initially results in apnea or hypoventilation and later causes tachypnea. It is postulated that the dual action of morphine is secondary to the effects of the drug concentration and to the effects of the drug on 2 different sites involved in the control of respiration. After a bolus of morphine, its initial high concentration causes respiratory depression and apnea. As the drug is metabolized, the lower concentration is associated with stimulation of respiration, hence the tachypnea. Morphine is found to be inhibitory to the

respiratory neurons in the medulla and to the neurons located more rostrally that act to inhibit respiration.

Abnormal heart rate tracings associated with elevated serum creatine phosphokinase were noted to be significantly different in infants of drug-dependent mothers compared with unexposed infants. In addition, these changes were more intense among infants who had moderate to severe withdrawal. The elevated serum creatine phosphokinase is postulated secondary to the excess muscular activity of infants undergoing withdrawal.

Other physiologic alterations include elevated systolic blood pressure, an increase in plasma renin activity, and elevated catecholamine levels. In one report, these conditions persisted for 21 days after delivery, suggesting increased beta-adrenergic activity.

### Gastrointestinal Signs

The sucking of the infant withdrawing from narcotics is disorganized and poorly coordinated with swallowing. Both sucking rate and nutrient consumption are low. Often, milk drools around the corners of the infant's mouth. The infant seems incessantly hungry, and when feeding is unfulfilled it leads to mounting agitation, persistent crying, hyperactivity, and exhaustion. The poor nutrient intake and increased caloric expenditure from hyperactivity may occur and lead to significant weight loss. Vomiting and diarrhea also are often observed and may lead to dehydration, electrolyte imbalance, and excoriations around the buttocks.

### Vasomotor Signs

Significant vasomotor instability in a newborn experiencing withdrawal manifests as a stuffy nose, flushing, mottling, sweating, and episodes of sudden, circum-oral pallor.

### Cutaneous Signs

Newborns experiencing withdrawal may be hyperactive, and this may lead to facial scratches and abrasions on pressure points. Excoriations of the buttocks can occur if diarrhea is present.

## NEONATAL WITHDRAWAL FROM NONNARCOTIC DRUGS

Withdrawal from nonnarcotic drugs is similar to narcotic withdrawal except that convulsions are observed more often in the former. Infants born to mothers who have abused stimulants during pregnancy (eg, cocaine, amphetamines) also may manifest tremors, irritability, a high-pitched cry, and abnormal sleep patterns during the neonatal period. These are probably manifestations of drug effects rather than withdrawal.

### DIAGNOSIS

The diagnosis of drug withdrawal is based on signs and symptoms and the verification of fetal drug exposure. However, identifying drug exposure in an infant is not easy: there is significant under-reporting of maternal drug use because of fear of the consequences of such an admission. Even with maternal cooperation, information regarding the type and extent of drug use often is inaccurate. Similarly, many of the drugs to

which the fetus is exposed in utero do not produce immediate or recognizable effects. High-risk characteristics in the mother that should lead to the suspicion of drug abuse include little or no prenatal care, ethanol use, teenage pregnancy, history or presence of sexually transmitted infectious disease or hepatitis B, and abruptio placenta. A number of laboratory tests commonly are used to detect drug exposure in the infant. These include toxicologic analysis of the infant's urine, hair, and meconium. Urine screening can have a high false-negative rate because only the results for infants who have had recent exposure will be positive. Meconium testing is more likely to identify infants of drug-abusing mothers.

### DIFFERENTIAL DIAGNOSIS

Withdrawal from narcotic and nonnarcotic drugs needs to be distinguished from other entities such as hypoglycemia, hypocalcemia, hypomagnesemia, sepsis, meningitis, subarachnoid hemorrhage, infectious diarrhea, and intestinal obstruction. Blood chemistry, cerebrospinal fluid, radiographic studies, and cultures may be performed as indicated by the clinical circumstances.

Maternal use of phenothiazines (eg, chlorpromazine) may induce extrapyramidal dysfunctions in the newborn such as tremors, facial grimacing, increased muscle tone, cog-wheel rigidity, increased reflexes, and torticollis, all of which can resemble the withdrawal syndrome. The maternal medical history and identification of the drug's metabolites in the infant's serum or urine are necessary to establish the diagnosis.

## ASSESSMENT OF THE SEVERITY OF NEONATAL DRUG WITHDRAWAL

The manifestations of withdrawal can range in severity from none or mild to severe. It has been shown that neither the infant's gender, race, or Apgar score nor the mother's age, parity, or duration of heroin intake correlate with the severity of the infant's withdrawal. Likewise, control of the environment to reduce the amount of light or noise in the nursery does not improve the severity of withdrawal. Since adults undergoing withdrawal experience abdominal cramps, palpitation, nausea, and other discomforts, it can be speculated that the same discomforts also are experienced by the infant, which may abolish any potential benefits from stimuli (light or noise) reduction in the nursery. Although environmental control may not ameliorate the severity of withdrawal, a quiet and darker nursery, in general, is preferred. The severity of an infant's withdrawal from methadone correlates significantly with the methadone dose of the mother. Mothers taking higher doses of methadone are likely to have infants experiencing severe withdrawal. Neonatal withdrawal tends to be more intense if the mother was on 20 mg or more of methadone per day before delivery. The frequency of diarrhea and vomiting should be noted and the infant's weight checked at least every 8 hours. The temperature, heart rate, and respiratory rate should be taken every 4 hours. Laboratory examinations to detect serum electrolyte or pH imbalance should be performed as indicated.

The severity of the withdrawal can be assessed clinically by several scoring systems. The scoring system designed by Finnegan is an extensive evaluation that is particularly useful for research purposes in evaluating the severity of withdrawal as well as the response to treatment. However, the Finnegan scoring system contains 21 items to evaluate, including minor symptoms such as yawning, sneezing, sweating, and so on; because of the large number of items to be evaluated, the scores may not be filled out completely or uniformly. Likewise, the Finnegan assessment criteria do not include weight loss, which is an important manifestation of neonatal drug withdrawal. Using the Finnegan scoring system, treatment of the infant with medications is recommended, if the total score is greater than 8 for 3 consecutive times. This can be problematic since a total score of more than 8 may be achieved by the inclusion of minor signs of withdrawal such as yawning, mild tremors, sneezing, nasal stuffiness, and mottling, which per se do not warrant drug treatment. More stringent criteria should be adopted for pharmacologic treatment since once drugs are used, the infant stays in the hospital longer in order to control the withdrawal and to allow time for gradual weaning and prevent a rebound withdrawal. Thus, treatment of the infant with pharmacologic agents results in a prolonged hospital stay and longer separation of the mother from her infant (7–10 days). The latter adversely affects mother-infant bonding, which is already compromised by the maternal addiction problem. Child abuse has been one consequence of impaired mother-infant bonding. Furthermore, a prolonged hospital stay also increases hospital cost. Another system evaluates the infant's need for drug treatment and focuses on manifestations of withdrawal that are life threatening, such as irritability, tremors (convulsion), weight loss, vomiting, diarrhea, and tachypnea (Table 104-1). Measurement of infant movement with a motion detector has been used in research settings to objectively gauge the severity of withdrawal.

The effect of polydrug abuse on the severity of withdrawal is controversial. Abstinence scores of

infants whose mothers were on methadone and cocaine were similar to the scores of those infants whose mothers were on a high methadone dose. Similarly, multiple opiates did not alter the severity of withdrawal. However, higher abstinence scores have been reported in infants exposed to both cocaine and heroin compared to either drug alone. In 2 reports, no difference was observed in the severity of withdrawal in infants born to mothers who have used both cocaine and methadone or either singly, whereas in a third report, higher abstinence scores were noted in infants exposed to both drugs compared with those exposed to only one.

## SUPPORTIVE TREATMENT OF DRUG WITHDRAWAL

The care of the neonate with drug withdrawal is primarily supportive. This includes swaddling the infant, placing him or her in a prone position, and cuddling more often. Swaddling, particularly with the infant's extremities flexed and hands placed before its mouth, enhances the infant's hand-to-mouth facility, which is soothing. A similar soothing action can be achieved with a pacifier. Other measures include frequent small feedings of hypercaloric (24 cal/oz) formula to supply the additional caloric requirements, hydration, and observation of sleeping habits, temperature stability, weight loss, diarrhea, and change in clinical status that might suggest another disease process. Daily caloric intake should provide the 150 to 250 cal/kg required for proper growth in neonates exhibiting withdrawal.

## Pharmacologic Treatment of Drug Withdrawal

Only 25% of infants who exhibit withdrawal will need drug treatment. The remainder can be managed conservatively. The decision to use pharmacologic agents to treat withdrawal is based on the assessment of the severity of withdrawal. In the system of clinical assessment shown in Table 104-1, drugs are used to treat withdrawal if there is a moderate degree of vomiting,

**Table 104-1** Assessment of Clinical Severity for Neonatal Drug Withdrawal Syndrome

	MILD	MODERATE	SEVERE
Vomiting	Spitting up	Extensive vomiting for 3 successive feedings	Vomiting associated with imbalance of serum electrolytes
Diarrhea	Watery stools	Watery stools 5–6 times per day for 3 days; no electrolyte imbalance	Diarrhea associated with imbalance of serum electrolytes
Weight loss	<10% of birth weight	10%–15% of birth weight	>15% of birth weight
Irritability	Minimal	Marked but relieved by cuddling or feeding	Unrelieved by cuddling or feeding
Tremors or twitching	Mild tremors when stimulated	Marked tremors or twitching when stimulated	Convulsions
Tachypnea	60–80/minute	80–100/minute	>100/minute and associated with respiratory alkalosis

Treat with pharmacologic agents (see Table 104-2) if infant has:

1. Moderate vomiting, diarrhea, or weight loss

2. Any severe sign of withdrawal (eg, convulsion or severe vomiting, diarrhea, weight loss, irritability, tachypnea)

From Ostrea EM. Infants of drug-dependent mothers. In: Berg FD, Ingelfinger JR, Wald ER, eds. *Current Pediatric Therapy*. Vol. 14. Philadelphia: WB Saunders; 1993. Reprinted with permission.

diarrhea, or weight loss or any severe sign of withdrawal (convulsion, severe vomiting, diarrhea, weight loss, or irritability). The use of pharmacologic agents, as compared to supportive care only, seems to reduce the time to regain birth weight and the duration of supportive care, but increases the duration of hospital stay. The duration of treatment also is related to the severity of withdrawal, although the length of stay of infants in the nursery is not significantly different whether treatment is with methadone or morphine.

The drugs that are used to treat drug withdrawal in the infant are listed in Table 104-2. As a rule, drug selection should match the class of agent from which the infant is withdrawing. Thus, for narcotic withdrawal, narcotics are the drugs of choice, whereas for nonnarcotic withdrawal, nonnarcotic hypnotosedatives (eg, phenobarbital) are preferred. Combinations of opiate and nonopiate drugs have also been used. Improved neurobehavioral scores have been noted in infants treated for withdrawal with opiate and phenobarbital. Although the neurologic manifestations of narcotic withdrawal may be controlled successfully by a nonnarcotic agent, non-CNS manifestations of withdrawal (eg, diarrhea) are treated more effectively with narcotics.

Laudanum (tincture of opium) and methadone are the narcotics most commonly used to treat neonatal opiate withdrawal. The use of paregoric has been discouraged because of the potential toxic effects of some of its ingredients. Besides camphor, a potent CNS stimulant, paregoric contains isoquinolone derivatives (noscapine and papaverine), which are antispasmodics. It also contains a high concentration of ethanol (44% to 46%), a CNS depressant, and anise oil, which may cause habituation. Laudanum is the preferred drug for neonatal narcotic withdrawal. (Caution: Laudanum, USP is available only as a 10% solution that contains 1.0% morphine.) Laudanum must be first diluted 25-fold to a concentration of 0.04% to reduce its morphine content to equal the amount found in paregoric. At this dilution, the recommended initial dose of 0.04% laudanum is 0.1 mL/kg (0.04 mg/kg) with feedings every 4 hours. The dose may be increased by 2 drops/kg every 4 hours as needed to control withdrawal. After the infant has stabilized for 3 to 5 days, the dose may be slowly decreased without altering the frequency of administration. An abrupt decrease in dosage or discontinuance of the drug should be avoided because of the risk

of relapse. Lower peak doses of tincture of opiate and shorter dosing intervals have been associated with shorter hospital stays for infants with neonatal abstinence syndrome secondary to maternal methadone treatment. Oral morphine solution sulfate has been used in place of laudanum because of its more exact content of morphine. It is given as an oral solution at a dose of 0.03 to 0.1 mg/kg. The initial dose may be increased stepwise if withdrawal is not adequately controlled. If methadone is used, initial doses of 0.05 to 0.1 mg/kg may be given every 6 hours, with increases of 0.05 mg/kg until withdrawal signs are controlled. Thereafter, methadone may be given every 12 to 24 hours and discontinued after weaning to a daily dose of 0.05 mg/kg per day.

Neonatal abstinence syndrome can occur as well in infants who receive narcotics for analgesia or sedation (iatrogenic neonatal abstinence syndrome). The guidelines for effective weaning of infants from opioids are not well established. A suggested strategy is that all NICU patients who have received opioids for more than 3 to 5 days be systematically weaned from the opioid while being regularly evaluated for signs of withdrawal.

Nonnarcotic hypnotosedatives are used to treat neonatal withdrawal from nonnarcotic drugs (Table 104-2). The commonly used drugs are phenobarbital and chlorpromazine. Barbiturates can be used to treat withdrawal from nonbarbiturates (including alcohol) or vice versa. Although chlorpromazine is not a nonnarcotic hypnotosedative, its capacity to treat withdrawal may result from its ability to suppress REM sleep, which is exaggerated during withdrawal. However, the prolonged excretion time and many side effects of chlorpromazine, including cerebellar dysfunction, decreased seizure threshold, and hematologic problems, have limited its use in the treatment of withdrawal in the neonate. The Cochrane review does not recommend the use of chlorpromazine in the treatment of the neonatal abstinence syndrome owing to lack of randomized studies. Diazepam has not commonly been used because of reported side effects such as bradycardia, respiratory depression, and discoordinate sucking and swallowing. During the treatment of withdrawal, attention should also focus on the nutrition and fluid and electrolyte balance of the infant, particularly if vomiting, diarrhea, hyperpyrexia, and hyperhidrosis are present. Appropriate intravenous

**Table 104-2** Common Drugs for the Treatment of Neonatal Drug Withdrawal Syndrome

DRUGS	DOSAGE
<b>NARCOTICS</b>	
Laudanum (0.4 mg/mL morphine)	0.1 mL/kg (0.04 mg/kg) every 4 hours and may be increased by 0.1 mL/kg (0.04 mg/kg) every 4 hours to control withdrawal manifestations
Methadone	0.05–0.1 mg/kg every 6 hours, orally. Increase dose by 0.05 mg/kg until withdrawal signs are controlled.
<b>NONNARCOTICS</b>	
Phenobarbital	3–6 mg/kg/day in divided doses, every 6 hours, orally

fluids may be required to correct deficits or prevent the occurrence of imbalances.

The aim of treatment with drugs is to render the infant comfortable but not obtunded. Thus, the drug should be titrated, starting with the smallest recommended dose and increased accordingly, until the desired effect is achieved. Once the infant has been asymptomatic for 3 to 5 days, the drug can be slowly tapered in dose until completely discontinued. The total detoxification period can last for 2 to 3 weeks. After discontinuance of the drug, the infant should be observed for a day or 2 for possible recurrence of the withdrawal (rebound phenomenon). Once the infant is discharged from the nursery, the mother should be informed that some jitteriness and irritability may persist for as long as 8 to 16 weeks.

### Complications

The complications of neonatal drug withdrawal are related to the severity of the withdrawal. Biochemical aberrations in the serum electrolytes and pH and dehydration may occur after vomiting and diarrhea. Weight loss may be profound not only because of excess fluid losses, but also because of poor oral intake. Aspiration pneumonia may occur because of vomiting and incoordinate sucking and swallowing. Respiratory alkalosis can occur because of tachypnea. Convulsions may be present and are observed more often in withdrawal from nonnarcotic drugs. The use of naloxone in the delivery room is contraindicated in infants whose mothers are known to be opioid dependent. Administration of naloxone may result in neonatal seizures, because of abrupt drug withdrawal. In the absence of a specific history of opioid abuse, naloxone treatment remains a reasonable option in the delivery room management of a depressed infant whose mother has received a narcotic drug during labor. However, the physician should be prepared to treat withdrawal in the delivery room.

### Other Supportive Measures

The addicted woman has serious impediments to a successful mothering role. Similarly, the neurobehavioral abnormalities and withdrawal in her baby can prevent gratifying feedback, which is important in bonding. Thus, the mother and child should have early and repeated contacts. Social services and the appropriate child welfare authorities should be engaged to ensure that the necessary family supports and community resources are in place if the infant is discharged home with the mother. The infant's disposition is influenced by local community child welfare policies. Consideration is often given to whether the mother is in recovery, what drugs she is using, if she is enrolled in drug treatment, if she has resources, and whether the extent of her family or informed support network is sufficient. Staff personnel should also discuss with the mother her infant's condition and assure her that with control of withdrawal manifestations, the infant will begin to feed better and respond more positively to her.

If plans have been made to place the infant in a foster care home, then in the interim the infant will need

human contact and should receive stimulation through regular holding and cuddling by staff professionals.

### BREASTFEEDING

Most drugs taken by the mother will cross into her breastmilk. The concentration of illicit substance in the breast milk will depend on the amount and time of drug intake by the mother. There also is the danger of transmission of human immunodeficiency virus (HIV) through the breastmilk; thus, in the United States breastfeeding is not recommended in a mother who is HIV positive. In developing countries where infant malnutrition and contaminated water are equally, if not more, important problems, the risk of acquisition of HIV/AIDS has to be weighed against the benefits of breastfeeding. Seropositivity for hepatitis-B surface antigen or hepatitis C is not a contraindication to breastfeeding provided the infant is vaccinated and given hepatitis B immunoglobulin as soon as possible after delivery. For the infant whose mother has continued to use illicit substances throughout pregnancy, breastfeeding is probably unsafe. The American Academy of Pediatrics guidelines on breastfeeding in the mother who continues to use illicit drugs can be summarized as follows: Methadone is "usually compatible with breastfeeding"; benzodiazepines are of "unknown effect but may be harmful"; phenobarbitone has "significant effects documented—use with caution"; and amphetamines, cocaine, heroin, marijuana and phencyclidine are contraindicated because harmful effects have been documented in nursing infants.

For the woman who is in treatment for substance abuse and abstinent at the time of delivery, postpartum breastfeeding support, close monitoring of the mother for relapse and of the infant for adequate weight gain, and frank discussions concerning the risks posed by exposure to illicit substances through breastmilk are essential.

Methadone treatment in the mother is compatible with breastfeeding; no adverse effects have been reported in nursing infants when the mother is on a methadone dose of 20 mg per day or less. The concentration of methadone in breastmilk is low and does not correlate with maternal dose. Breastfed infants of women on methadone have lower Finnegan scores and reduced need for pharmacotherapy compared to their formula-fed counterparts. It is suggested that the mother take the dose of methadone after the evening feeding and supplement breastfeeding with a bottle at the next feeding.

### DECISIONS REGARDING THE INFANT'S CAREGIVER

The ability of the drug-addicted woman to provide adequate care for her infant has often been questioned. Frequently, these women are denied their rights and responsibility to care for their infants on the basis of an unstable home and lifestyle and emotional and psychological weakness. Current evidence suggests that this practice may be counterproductive. A study that determined the outcome of such infants on the basis of the type of caregiver showed that the outcome (growth, development, and frequency of

medical illnesses and child abuse) of infants cared for by their own mother with the help of a caregiver (either a husband or relative) was better than for those in foster care. Thus, with appropriate guidance and supervision and the presence of a supportive person, the addicted mother is capable of providing adequate care for her infant, particularly if she is highly motivated. Coordinated outpatient care of the infant also has been used to shorten the stay of the infant in the nursery. Although a high incidence of signs suggestive of child abuse (cigarette burns or hematoma) has been observed in infants born to drug-dependent mothers, these have occurred in situations where the infant was cared for exclusively by the mother, and very few occurred in infants whose mothers had help available. Thus, it is important that a support person be available at home to help the mother in the care of her infant and prevent child abuse or neglect. It is also important to understand, identify, and treat risk factors that could destabilize the home. This is particularly true of domestic violence, which is not only linked to higher rates of child abuse and neglect but can have a cumulative effect in regard to adverse childhood experiences that can cause long-term problems with the physical and mental health of children.

### **SOCIAL AND PROTECTIVE SERVICE REFERRAL AND FOLLOW-UP**

All infants of drug-dependent mothers should have a social service referral to assess the adequacy of parenting and care of the infant at home. The discharge of the infant to the mother's care, with the help of a support person, is the primary objective unless serious conditions dictate otherwise. The discharge of the infant to a person other than the mother (foster parent) or an agency should be attempted only when it is apparent that the infant will be neglected, poorly cared for, or abused. Most mothers hesitate to admit to the use of drugs during pregnancy because of fear that their infants will be taken away from them. They should be reassured otherwise; in fact, they should be encouraged to be responsible for the primary care of their infants. The social worker and physician also should advise the mother regarding the availability of medical and social services in the community, including substance abuse counseling, referrals for mental health, other supportive treatment, and family planning. Maternal initiation of drug treatment and supportive services in the perinatal period can have positive results, especially since the mother has the motivation of being a good parent to her newborn to help with compliance. There will be situations in which the mother is not willing or able to engage in the needed treatment or support services. Thus, it is equally important for the health care provider to work collaboratively with colleagues in child protection to optimize flow of accurate information to the social service agencies that will be working on behalf of the child for safety and permanency.

As part of child protection laws operative in many states, infants born to drug-dependent mothers are considered potentially abused and are required by law to be reported to a child protection agency after

birth. The agency usually requires a positive drug screen in the infant before any legal action can be taken against the mother. If necessary, confirmatory tests of positive drug test results should be done to validate the test results and avoid unnecessary referral to protective service. Thus, maternal admission of the use of illicit drugs during pregnancy is not sufficient to generate a child protection agency referral because the mother can subsequently deny her illicit drug use. Referral to a child protection agency is helpful when the intent is to ensure the adequacy of care of the infant at home. If a prenatal determination is made that the baby will be placed in foster care and the mother is informed about it, she may refrain from continuing prenatal care with her providers, choosing to deliver at another facility where she and her history are not known. This puts the mother (and baby) at higher risk for pregnancy-related complications and causes a greater risk of fetal death or morbidity.

### **LONG-TERM PROBLEMS**

The infant of the drug-dependent mother is at risk for long-term problems including child abuse, delays in physical, mental, and motor development, and learning disabilities. Drug-exposed newborns have increased neonatal mortality from sudden infant death syndrome, particularly low-birth-weight infants. The infant also is at risk for ongoing exposure to illicit drugs in the household as a result of accidental ingestion or passive exposure, particularly to smoked crack cocaine. Follow-up of these infants should be planned, not only to assess their medical well-being, but to ascertain the occurrence of such complications and initiate appropriate interventions.

Neurobehavioral problems in infants of drug-dependent mothers have been noted ranging from hyperactivity and impulsivity to poor sustained attention, which may or may not fulfill diagnostic criteria for attention-deficit/hyperactivity disorder (ADHD). Prenatal smoking and alcohol use are 2 of the most commonly studied agents linked to ADHD and ADHD-like symptoms. In a small cohort, opiate-exposed infants were significantly more likely to have neurodevelopmental impairment compared to healthy control infants when assessed at 18 months and 3 years of age. The findings of the Maternal Lifestyle Study group of the National Institutes of Health showed that opiate-exposed infants who were longitudinally followed at 1 and 3 years of age scored 3.8 Psychomotor Developmental Index points below the nonexposed group, but the difference was not statistically significant after controlling for covariates. Children with prenatal opiate exposure had smaller intracranial and brain volumes, including smaller cerebral cortex, amygdala, brainstem, cerebellar cortex, cerebellar white matter, and other regions of the brain.

With regard to cocaine, deficits in the quality of parent-child interactions have been noted in preschool-age children exposed prenatally. At 7 months, cocaine-exposed infants displayed higher arousal or reactivity and lower regulation during a procedure designed to arouse anger and frustration. Those exposed to cocaine responded with negative affect (anger and

sadness) more quickly as the level of stress increased. Sleep problems were also noted in 18-month- to 9-year-old children with prenatal drug exposure. During middle childhood, heavier prenatal cocaine exposure is associated with mild compromise of selective areas of neurocognitive development, specifically cognitive regulation. As part of the longitudinal maternal lifestyle study, prenatal cocaine exposure increased the likelihood of the children receiving individualized education programs, special education conditions, support services, special education classes, and speech and language services. The cocaine-exposed children also had 2.8 times greater risk of developing a learning disability by age 7 than non-cocaine-exposed children.

Neurocognitive testing showed that children with prenatal methamphetamine exposure scored lower on sustained attention, long-term spatial and verbal memory, and visual motor integration. Neuroimaging has produced reports of smaller striatum and hippocampus volumes and decreased numbers of dopamine D2 receptors and dopamine transporter density.

To optimize long-term outcomes in infants of drug-dependent mothers, early intervention services should be identified and enacted; this can positively affect outcomes for drug-exposed newborns at risk for developmental delay. Perinatal health care providers should work collaboratively to educate state legislators that identification of drug use alone is not adequate to cure the problem of addiction or to specifically identify parents who will abuse or neglect their children. It is essential to develop and utilize screening tools to identify parents at risk, fund evidence-based treatment for addiction, and link high-risk parents to effective educational programming to preserve families and make better use of state resources.

### Chapter 105

## TRANSIENT METABOLIC DISTURBANCES IN THE NEWBORN

Zuzanna Kubicka, MD; George A. Little, MD

At birth, placental function, including transport of glucose, calcium, phosphorus, and magnesium, is suddenly interrupted. Usually this process occurs uneventfully; however, pediatricians and other physicians must be aware of the physiologic mechanism of transition and possible problems that may occur clinically.

### GLUCOSE METABOLISM IN THE FETUS AND METABOLIC ADAPTATION AT BIRTH

Carbohydrate is transported to the fetus as *glucose* by transplacental facilitative diffusion across a concentration gradient. Glucose transport capacity increases with gestational age, with a portion used for placental metabolism. When placental function and fetal growth are normal, fetal glucose production is limited.

Glucose-sensing and insulin-secreting pathways are present in the human fetus as early as 14 to 18 weeks' gestation, but secretion of insulin in response to glucose is attenuated. During fetal development, pancreatic  $\beta$  cells mature, with biphasic insulin release developing after birth. When the fetus is subjected to reduced glucose supply, hypoglycemia and hypoinsulinemia may develop despite fetal glucose production.

Healthy, term neonates transition to the extrauterine environment without need for metabolic monitoring. Hepatic glycogen content increases with gestational age, and most deposition occurs toward the end of gestation.

Neonatal glucose requirements of approximately 5 to 8 mg/kg per minute, mostly for cerebral use, must be met endogenously when the placental glucose supply ceases. Immediately after birth, a 3- to 5-fold surge in glucagon and catecholamines takes

place, which initiates glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis. Endogenous growth hormone and cortisol facilitate the onset of gluconeogenesis within several hours, and insulin secretion and serum concentrations fall. Enzymatic systems for glycogen breakdown and gluconeogenesis must be in place, along with a supply of substrate in the form of fat and amino acids. Human milk has an important role in the induction of ketogenesis, which spares glucose for brain consumption and facilitates gluconeogenesis.

Preterm and some intrauterine growth-restricted neonates have transitional metabolic processes that are not fully developed, and less glycogen stores are available for glucose mobilization after birth. Glucose regulation problems also occur with a wide range of antepartum, intrapartum, and postnatal problems such as maternal diabetes, hypoxic stress, and sepsis.

### NEONATAL HYPOGLYCEMIA

In 2009 a National Institute of Child Health and Human Development Workshop on neonatal hypoglycemia focused on knowledge gaps and research needs for understanding and treating neonatal hypoglycemia. The goal of the workshop was to identify future research areas, including glucose metabolism in the brain, the definition of clinically significant hypoglycemia, and improved methods for plasma glucose monitoring and treatment. The definition, significance, and management of hypoglycemia persist as controversial issues in contemporary neonatal pediatrics.

#### Definition

The definitive diagnosis of neonatal hypoglycemia must satisfy the Whipple triad: the presence of clinical manifestations; coincidence with reliable low plasma glucose concentrations; and resolution of manifestations once normoglycemia has been reestablished.

This definition does not include so-called *asymptomatic* hypoglycemia without clinical manifestations, even with very low plasma glucose concentrations (see further discussion in the Evaluation section). Controversy remains as to whether transient asymptomatic hypoglycemia causes sequelae.

Attempts have been made to identify a threshold blood glucose concentration below which a substantial likelihood of functional impairment exists. The evidence for a glucose level that causes irreversible neuronal injury remains poorly defined. Data from animal studies support the theory that sustained hypoglycemia is associated with neuronal necrosis. No prospective study in human infants has been conducted to determine such a threshold.

Neuropathology findings in symptomatic hypoglycemic infants are suggestive of widespread acute neuronal and glial injury for the most part in occipital lobes. The most consistent finding of neuroimaging studies on symptomatic hypoglycemic newborns is cortical and white matter occipital abnormalities. Current reports on term infants with symptomatic hypoglycemia extend the spectrum of magnetic resonance imaging (MRI) abnormalities to global white matter, deep nuclear gray matter, and cortical infarction. The early MRI abnormalities in this study were

**Figure 105-1** Incidence of hypoglycemia by birth weight, gestational age, and intrauterine growth. (From Lubchenco LO, Bard H. Incidence of hypoglycemia in newborn infants classified by birth weight and gestational age. *Pediatrics*. 1971;47:831–838.)

much more predictive for neurodevelopmental outcomes than severity or duration of hypoglycemia. This suggests that MRI may become a routine investigation for the neonate with symptomatic hypoglycemia.

Numerous textbooks and papers use the arbitrary plasma glucose level of 40 to 45 mg/dL or blood glucose value less than 35 mg/dL as a defining threshold for intervention, with the range as wide as 27 to 47 mg/dL.

An important point to remember is that a healthy term newborn exhibits an immediate postnatal fall in blood glucose concentration during the first 2 to 4 hours from values close to maternal levels to approximately 30 to 45 mg/dL (1.7–2.5 mmol/L).

#### Frequency

Overall incidence has been estimated to be 1 to 5 per 1,000 live births. The classic Lubchenco and Bard studies of neonatal hypoglycemia illustrate that intrauterine birth-weight/gestational-age status may serve as an indicator (Figure 105-1).

#### Differential Diagnosis

Table 105-1 presents a comprehensive list of causes of neonatal hypoglycemia. The information provided can be used to identify at-risk infants for whom routine monitoring of blood glucose is recommended. In clinical practice this will most commonly include small-for-gestational-age (SGA) infants, infants born to a diabetic mother (IDMs)/large-for-gestational-age (LGA) infants, and late-preterm infants 34 to 36 weeks' (34 $\frac{0}{7}$ –36 $\frac{6}{7}$ ) gestation.

Transient hypoglycemia usually resolves within 2 to 3 days. A requirement of more than 8 to 10 mg/kg per

**Table 105-1** Differential Diagnosis of Neonatal Hypoglycemia

ETIOLOGY	EXPLANATION	DURATION OF HYPOGLYCEMIA
Associated with maternal problems:	Hyperinsulinism and resulting inhibition of glycogenolysis, lipolysis, glyconeogenesis, and increased peripheral glucose utilization	Transient (<7 days' duration)
1. Diabetes in pregnancy, IDM	Decreased glucose supply	
2. Drug treatment: Oral hypoglycemic agents	Hyperinsulinism	
• Terbutaline	Unknown mechanism	
• Ritodrine	Possibly prevention of sympathetic stimulation of glycogenolysis, prevention of recovery from insulin induced, decreases in free fatty acid and glycerol	
• Propranolol	Hyperinsulinism	
3. Intrapartum administration of glucose		
Associated with neonatal problems:		
1. Perinatal hypoxia-ischemia	Higher glucose utilization or decreased production	Transient (<7 days' duration)
2. Infection	Hyperinsulinism, possibly increased number of pancreatic $\beta$ -cells	
3. Hypothermia		
4. Hyperviscosity		
5. Erythroblastosis fetalis, hydrops		
6. Iatrogenic:		
• Malpositioned umbilical artery catheter	Infusion of high glucose concentration into celiac, superior mesenteric artery; hyperinsulinism	
• Abrupt cessation of high glucose infusion	Hyperinsulinism	
• Exchange transfusion	Blood containing high glucose concentration, hyperinsulinism	
Intrauterine growth restriction, prematurity, inadequate caloric intake	Limited glycogen stores Altered insulin secretion Altered hormonal response to hypoglycemia	Transient (<7 days' duration)
Genetic disorders: Beckwith-Weidemann syndrome, Perlman syndrome, Sotos syndrome (rare), genetic forms of hyperinsulinism (dysfunction of pancreatic ATP-sensitive potassium channel), insulin-secreting tumors	Hyperinsulinism	Prolonged
Endocrine disorders: hypopituitarism, adrenal insufficiency, hypothalamic deficiency	Higher glucose utilization or decreased production	Prolonged
Inborn errors of metabolism, including fatty acid oxidation deficiency and congenital glycosylation disorders	Higher glucose utilization or decreased production	Prolonged

ATP, adenosine triphosphate; IDM, infant of diabetic mother.

Neonatal hypoglycemia. *NeoReviews*. 1999;(July):e6–e15; Wilker RE. Hypoglycemia and hyperglycemia. In: Cloherty JP, Eichenwald EC, Stark AR, eds. *Manual of Neonatal Care*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2012; Cornblath M, Schwartz R. Hypoglycemia in the neonate. *J Pediatr Endocrinol*. 1993;6:113–129.

minute suggests hyperinsulinism and is seen most commonly in the IDM. Persistence for more than 7 days or recurrence usually warrants subspecialty endocrine or metabolic evaluation.

## Evaluation

### Physical Examination

The typical clinical manifestations of hypoglycemia are summarized in Box 105-1. Birth-weight/gestation-age indicators previously discussed (see Figure 105-1), including their morphologic expressions (LGA, SGA, intrauterine growth restricted), must be considered.

An important point to realize is that the quiet or inactive newborn who is not exhibiting any of the listed symptoms may, in fact, be hypoglycemic. On the other hand these signs may occur with other common neonatal disorders, including sepsis, intracranial hemorrhage, or hypocalcemia. Infants exhibiting one

### BOX 105-1 Clinical Signs Associated With Hypoglycemia<sup>a</sup>

- Changes in behavior—irritability, lethargy
- Changes in neurologic status—hypotonia, limpness, tremor, jitteriness, seizures
- Cardiovascular signs—tachycardia, bradycardia
- Abnormal respiratory patterns—apnea, cyanotic spells, tachypnea, respiratory distress
- Feeding poorly, especially after feeding well
- Hypothermia

<sup>a</sup>Clinical signs should be alleviated with concomitant correction of plasma glucose levels.

Adapted from Cornblath M, Hawdon JM, Williams AF, et al. Controversies regarding definition of neonatal hypoglycemia: suggested operational thresholds. *Pediatrics*. 2000;105:1141–1145.

or more of these signs should have blood glucose screened.

### Laboratory Evaluation

Glucose reagent strips screen for low blood glucose concentration and provide a valuable estimate. Diagnosis depends on plasma glucose values. Whole-blood glucose levels are 10% to 15% lower than plasma glucose levels. Blood samples should be processed quickly because of possible glycolysis. False elevation can result from line sampling without preflushing.

Blood glucose concentrations reflect enteral feeds, reaching a peak by approximately 1 hour after feeding and a nadir just before the next feeding. Given that the purpose of blood glucose monitoring is to identify the lowest blood glucose level, prefeed measurement is recommended.

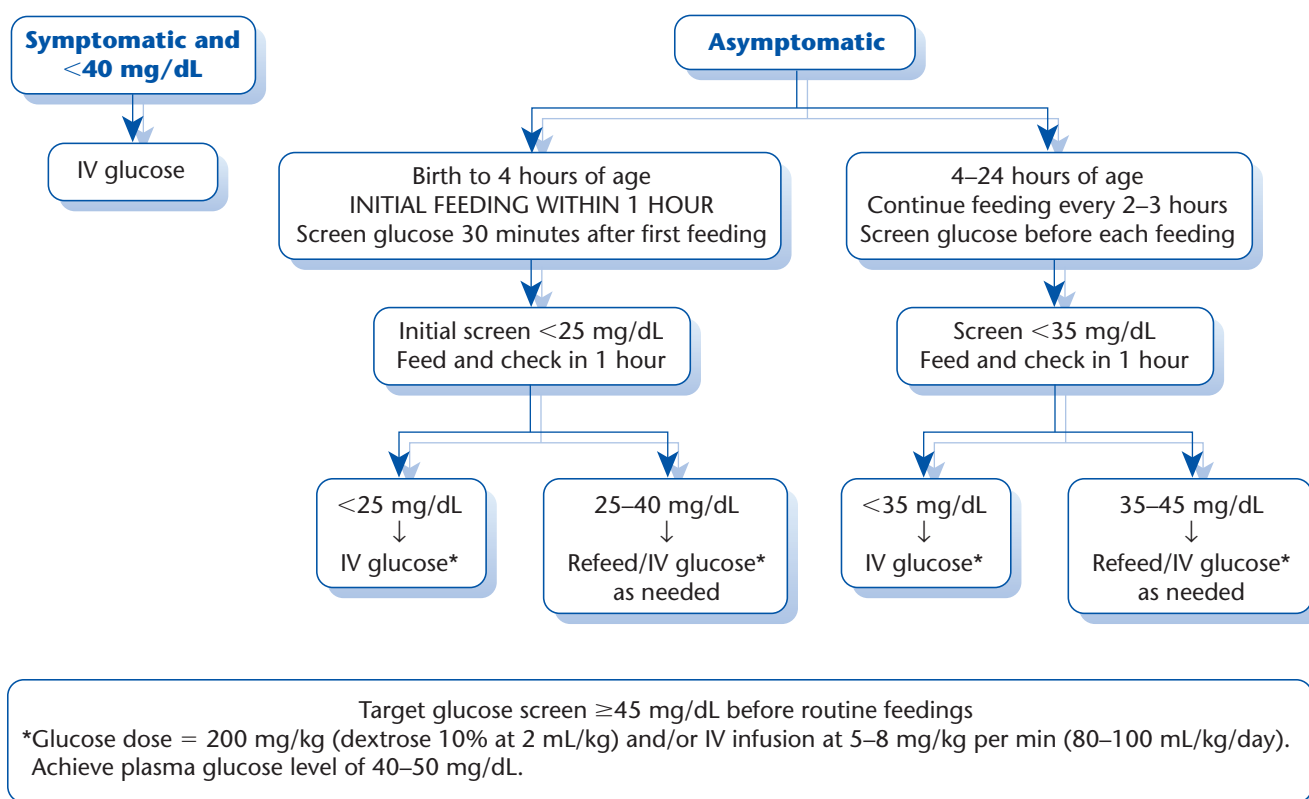

Continuous glucose monitoring in newborn babies at risk for hypoglycemia (<32 weeks' gestational age, IDM, SGA, LGA) has been recently investigated. The monitor, which provides 288 interstitial glucose concentration reading points per day, detected more episodes of low glucose concentration than intermittent blood glucose measurement and allows

measuring the duration, severity, and frequency of hypoglycemia in an individual baby. The sensor was well tolerated by patients, with single insertion providing up to 7 days of continuous reading. However, the physiologic importance of identifying previously undetected hypoglycemic episodes is unknown and could potentially lead to unnecessary treatment without changing the long-term outcomes. Further research is needed before adopting this method into clinical practice.

### Management

Pragmatic operational thresholds (blood glucose concentrations at which clinical interventions should be considered) for various clinical scenarios have been recently proposed.

Figure 105-2 provides a summary of management of neonatal hypoglycemia in various clinical scenarios in 2 time periods (birth to 4 hours and 4–24 hours), accounting for physiologic changes in glucose levels occurring over the first 12 hours after birth. For practicality, the management includes only the most common in clinical practice at-risk groups of infants (SGA, LGA, IDM, and late preterm).

Symptoms of hypoglycemia include: irritability, tremors, jitteriness, exaggerated Moro reflex, high-pitched cry, seizures, lethargy, floppiness, cyanosis, apnea, poor feeding.

**Figure 105-2** Screening and management of postnatal glucose homeostasis in late-preterm (LPT; 34–36<sup>6</sup>/<sub>7</sub> wk) and term small-for-gestational age (SGA) infants and infants who were born to mothers with diabetes (IDM)/large-for-gestational age (LGA) infants. LPT and SGA (screen, 0–24 hr), IDM and LGA >34 wk (screen, 0–12 hr). (From Adamkin D; Committee on Fetus and Newborn. Postnatal glucose homeostasis in late-preterm and term infants. *Pediatrics*. 2011;127[3]:575–579.)

In large numbers of other maternal or neonatal conditions listed as at-risk for hypoglycemia (Table 105-1), clinical symptoms are common, and most infants are already being monitored for plasma glucose levels. However, the thresholds for clinical interventions should be similar in this group of infants.

### Term Newborn

Feeding is the main preventive strategy for healthy, term newborns without risk factors or clinical signs suggesting problems. Breastfed newborns demonstrate lower blood glucose and higher ketone body concentrations than those who are formula fed.

### Newborns With Abnormal Clinical Signs

Symptomatic newborns should have a glucose reagent strip screen while awaiting laboratory determination. If the plasma value is less than 40 mg/dL (2.2 mmol/L), then clinical intervention to increase the blood glucose concentration is indicated.

Enteral feeds may be continued or introduced when clinically appropriate, and parenteral treatment is not a reason to delay them. Gradual rather than rapid reductions in the rate of glucose infusion help maintain stability and avoid labile glucose concentrations.

### Asymptomatic Infants With Risk Factors for Compromised Metabolic Adaptation

Routine determination of plasma glucose concentration should be performed for infants considered at risk. At-risk infants should be fed by 1 hour of age and screened 30 minutes after feeding. If the initial plasma glucose concentration is less than 25 mg/dL (1.4 mmol/L) before 4 hours of age or less than 35 mg/dL (1.9 mmol/L) within 4 to 24 hours of age, the asymptomatic at-risk infant should be fed again, and plasma glucose should be checked 1 hour after refeeding. Subsequent plasma glucose lower than 25 mg/dL within the first 4 hours of life, or less than 35 mg/dL within 4 to 24 hours of age, should prompt intravenous glucose treatment.

The target glucose level before feedings should be greater than 45 mg/dL (2.5 mmol/L).

Glucose monitoring should continue until at least 12 hours of age for IDM/LGA patients if they maintain prefeeding plasma glucose concentration greater than 40 mg/dL. Late preterm and SGA infants require plasma glucose monitoring for at least 24 hours because they remain more vulnerable to hypoglycemia especially if adequate oral feedings are not yet well established.

Maintaining therapeutic levels in excess of 60 mg/dL (3.3 mmol/L) may be indicated for symptomatic infants with documented hyperinsulinemic hypoglycemia; however, it should not be the therapeutic goal for most newborns with transient or brief episodes of low plasma glucose concentrations.

Intravenous glucose treatment should consist of minibolus of D<sub>10</sub>W 2 mL/kg and/or intravenous infusion of D<sub>10</sub>W at 5 to 8 mg/kg per minute (80–100 mL/kg/day). Excessive intravenous glucose infusions should be avoided to minimize pancreatic stimulation.

### Preterm Infants

The same strategies and thresholds mentioned previously apply to preterm newborns. Intravenous glucose infusion is often necessary owing to risk factors for development of hypoglycemia, including poor glycogen stores and limited oral feeding ability. Most well-nourished but preterm infants require at least 6 to 8 mg/kg per minute of glucose initially.

## HYPERGLYCEMIA

### Definition

A whole-blood glucose level greater than 125 mg/dL or a plasma glucose level of greater than 145 mg/dL is considered to be outside normal limits by most authors.

### Differential Diagnosis

Common causes of hyperglycemia are presented in Table 105-2.

Although more common than hypoglycemia, a large portion of hyperglycemia occurs in low-birth-weight infants receiving parenteral glucose. Infusion rates higher than 6.6 mg/kg per minute in infants less than 1,100 g and

**Table 105-2** Differential Diagnosis of Neonatal Hyperglycemia

CAUSE	MECHANISM
Prematurity, very low birth weight (<1,500 g)	Variable insulin response to persistent endogenous glucose production; high catecholamine and other stress hormone levels
Sepsis	Decreased insulin release or decreased glucose utilization; elevation of stress hormones
Hypoxia	Increased glucose production or absent increased utilization
Surgical procedures	Increased release of stress hormones; administration of intravenous glucose
Drugs: steroids, caffeine, theophylline, phenytoin	Increased glycogenolysis or gluconeogenesis
	Increased insulin resistance
	Increased insulin resistance and decreased insulin release
Hyperosmolar formula (inappropriate formula dilution)	Increased glucose load
Rare endocrine disorders: transient neonatal diabetes mellitus, diabetes related to pancreatic lesions	Decreased insulin release

Derived from Wilker RE. Hypoglycemia and hyperglycemia. In: Cloherty JP, Eichenwald EC, Hansen AR, Stark AR, eds. *Manual of Neonatal Care*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2012.

more than 6 mg/kg per minute in healthy, full-term newborns may cause iatrogenic hyperglycemia.

### Evaluation

#### Physical Examination

Clinical dehydration caused by osmotic diuresis is a serious complication of hyperglycemia; each 18-mg/dL rise in the blood glucose concentration increases serum osmolality by 1 mOsm/L and can contribute to hyperosmolality of more than 300 mOsm/L. Researchers have hypothesized that hyperglycemia, by increasing osmolality, causes the water to move from the intracellular to the extracellular compartment. This *contraction* of intracellular volume may be associated with risk for intracranial hemorrhage, particularly in the very low-birth-weight infant.

#### Laboratory Evaluation

In addition to blood determination for hyperglycemia, urine monitoring for glucosuria caused by exceeding renal tubular reabsorption capability of glucose may be helpful.

### Management

Prevention strategies and treatment of hyperglycemia are summarized in Box 105-2.

#### BOX 105-2 Prevention and Management of Neonatal Hyperglycemia

##### PREVENTION

- Avoid sudden changes in glucose concentration.
- Avoid glucose infusion rates  $>8$  mg/kg/min in premature and full-term infants.
- Use initially 5% glucose infusion concentration for infants  $<1,000$  g.
- Avoid using hypotonic fluids ( $<5\%$  dextrose).
- Start parenteral nutrition as soon as possible; some amino acids promote insulin secretion.
- Continue enteral feedings if not contraindicated because this promotes insulin secretion.

##### MANAGEMENT

- Decrease the glucose infusion to 4 to 6 mg/kg/min or by 2 mg/kg/min every 4 to 6 hr.
- If glucose level is persistent above 250 mg/dL despite all the measures to decrease the glucose intake, then consider insulin therapy.
- Continuous intravenous insulin infusion of 0.01 to 0.1 units/kg/hr (with close monitoring of plasma glucose levels, potassium levels).
- Subcutaneous insulin, 0.1 to 0.2 units/kg every 6 hr, is used most commonly in neonatal diabetes (with close monitoring of plasma glucose levels and potassium levels).

Adapted from Wilker RE. Hypoglycemia and hyperglycemia. In: Cloherty JP, Eichenwald EC, Stark AR, eds. *Manual of Neonatal Care*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2012; Pildes RS. Hypoglycemia and hyperglycemia in tiny infants. *Clin Perinatol*. 1986;3:351–375.

## CALCIUM AND PHOSPHORUS METABOLISM IN THE FETUS AND METABOLIC ADAPTATION AT BIRTH

Active calcium and phosphorus transport to the fetus is necessary for fetal growth and increases through gestation to a peak in the third trimester. Premature newborns are therefore at risk for deficiency, which can worsen after birth as a result of renal losses and deficient intestinal absorption.

Neonatal serum calcium homeostasis is maintained by exogenous intake or absorption from bones, or by both processes. In the first day, serum calcium decreases (low intake and cessation of maternal-fetal transport), and ionized calcium reaches the lowest level of 1.10 to 1.36 mmol/L (4.4–5.4 mg/dL) at approximately 24 hours of age, rising slowly thereafter.

Fetal phosphorus concentration is higher than the maternal concentration. Postnatal absorption takes place primarily in the jejunum, with low excretion levels in the newborn. During the first day of life, neonatal serum phosphorus concentration increases before increased absorption, probably related to its release during breakdown of tissue glycogen. This increased phosphorus concentration also probably contributes to decreased calcium concentration.

Calcium is the most abundant mineral in the human body, with 99% contained in the bones. Eighty-five percent to 90% of phosphorus is found in the skeleton. Calcium-phosphorus serum concentration is tightly regulated by parathyroid hormone (PTH), vitamin D metabolites, and calcitonin.

### VITAMIN D SUPPLEMENTATION

The American Academy of Pediatrics (AAP) recommendation published in 2008 is to initiate vitamin D supplementation of 400 units daily beginning in the first few days of life in breastfed and partially breastfed infants as well as formula-fed infants consuming less than 1,000 mL/day. The new recommendations come from emerging data about higher rates of vitamin D deficiency during pregnancy, suggesting that the rates of deficiency among women in child-bearing ages are up to 12% and are even higher among blacks. There is also growing evidence that 400 units/day of vitamin D is sufficient to prevent rickets and maintain normal vitamin D level.

Furthermore, prematurely born infants are even more likely to be vitamin D deficient because of limited transplacental transport. Exclusive breastfeeding without adequate sun exposure and vitamin D supplementation is another risk factor for deficiency, with vitamin D content on average 22 units per 1,000 mL of breast milk.

## NEONATAL HYPOCALCEMIA

### Definition and Diagnosis

Calcium circulates in blood in 3 fractions: protein bound (40%–45%); complexed with anions such as lactate, citrate, and bicarbonate (5%–10%); and ionized (50%). The last of these fractions is the only physiologically active fraction. With low serum protein, the total

calcium may be decreased, whereas the ionized fraction remains within normal limits. With normal total calcium, the ionized fraction may be decreased by alkalosis, administration of bicarbonate, or chelating agents present in blood products.

Hypocalcemia in the term newborn is best defined as serum ionized calcium concentration of less than 1.1 mmol/L (4.4 mg/dL). (See later discussion under Laboratory Evaluation.)

### Differential Diagnosis

Common causes of neonatal hypocalcemia are summarized in Table 105-3.

### Evaluation

#### Physical Examination

Physiologically the clinical signs of hypocalcemia are related to increased cell membrane excitability because low serum calcium levels increase cellular permeability to sodium ions. Signs of neonatal hypocalcemia are

often nonspecific and may include jitteriness, hyperreflexia, increased tone, and generalized or focal seizures, as well as apnea and rarely laryngospasm. Occasionally the newborn may exhibit classic tetany and positive Chvostek and Trousseau signs. Electrocardiographic readings may be significant for prolonged QTc interval. These signs may also be present with other disorders, including hypoglycemia.

#### Laboratory Evaluation

Ionized calcium values of less than 1.1 mmol/L in full-term infants and less than 1.07 mmol/L (4.28 mg/dL) in preterm infants should be used as reference value for hypocalcemia. The traditional definition of total serum calcium less than 2 mmol/L (8 mg/dL) for full-term infants and less than 1.75 mmol/L (7 mg/dL) for preterm infants is of limited value and should be used only if ionized calcium values are not available.

Measuring magnesium levels in the setting of hypocalcemia is important because correction of low

**Table 105-3** Differential Diagnosis of Neonatal Hypocalcemia

#### EARLY HYPOCALCEMIA ( $\leq 4$ DAYS AFTER BIRTH)

#### MECHANISM

Prematurity, intrauterine growth restriction	Low stores in more premature infants, low intake, increased phosphorus load, increased calcitonin levels, transient hypoparathyroidism, end-organ resistance to vitamin D
Maternal diabetes	Maternal hypomagnesemia during pregnancy, hypoparathyroidism, hyperphosphatemia, abnormal vitamin D metabolism
Perinatal asphyxia	Decreased intake, increased phosphorus load, increased calcitonin concentration
Maternal anticonvulsants (phenobarbital and diphenylhydantoin)	Increase hepatic catabolism of vitamin D

#### LATE HYPOCALCEMIA ( $> 4$ DAYS AFTER BIRTH)

#### MECHANISM

Cow milk–based formulas (particularly undiluted cow milk or evaporated milk)	Hyperphosphatemia
Hypomagnesemia	Impaired parathyroid hormone (PTH) secretion and peripheral PTH action
Hypoparathyroidism:	
• Transient congenital	• Hypocalcemia and hyperphosphatemia, low PTH, with PTH improving spontaneously
• Secondary	• Maternal hyperparathyroidism with maternal or fetal hypercalcemia and subsequent neonatal hypoparathyroidism
• Congenital primary—parathyroid agenesis or part of DiGeorge sequence, PTH gene mutation	• Decreased PTH
Other causes:	
• Vitamin D deficiency (renal disease, hepatobiliary disease, malabsorption, maternal vitamin D deficiency)	• Decreased calcium absorption
• Alkalosis	• Decreased ionized calcium, decreased calcium reabsorption from bones
• Citrated blood transfusion	• Chelated ionized calcium
• Lipid infusions	• Enhanced calcium-albumin binding
• Phototherapy	• Possibly increased melatonin, which causes increased bone calcium uptake
• Furosemide, xanthenes	• Promotion of calciuresis

Derived from Rigo J, Mohamed WM, De Curtis M. Disorders of calcium, phosphorus and magnesium metabolism. In: Fanaroff AA, Martin RJ, eds. *Neonatal-Perinatal Medicine*. 9th ed. St Louis, MO: Mosby; 2011.

serum calcium might not be possible without correcting hypomagnesemia. Low serum calcium may also be associated with seizures, although it is not the cause.

### Management

Management is complicated by several factors. Most cases of neonatal hypocalcemia are asymptomatic and self-resolving by day 3 of life. Similar signs may coexist with other neonatal conditions. Asymptomatic hypocalcemia in a well newborn usually resolves spontaneously without specific treatment. With the serum calcium level below 6.5 mg/dL (usually the asymptomatic very low-birth-weight newborn), some authors recommend continuous calcium infusion with the dose of 5 mL/kg/day of 10% calcium gluconate.

The treatment of symptomatic hypocalcemia consists of administering calcium salts (Table 105-4, Figure 105-3). Symptoms that are unresponsive to calcium therapy may be the result of hypomagnesemia. (See later discussion of management of hypomagnesemia.)

Bradycardia may be a serious systemic complication of intravenous calcium administration. Possible local complications include umbilical arterial spasm with rapid administration, extravasations into soft tissues, and hepatic necrosis if umbilical venous catheter lodged in the branch of the portal catheter.

The management of late-onset hypocalcemia usually consists of treating the underlying disorder.

## NEONATAL HYPERCALCEMIA

### Definition

Serum ionized calcium concentration greater than 1.35 mmol/L (5.4 mg/dL) with or without a total serum calcium level greater than 2.75 mmol/L (11 mg/dL) is considered abnormal.

### Differential Diagnosis

Neonatal hypercalcemia is usually iatrogenic. Excessive administration of calcium or vitamin D<sub>3</sub> should be excluded before extensive investigation for other etiology such as maternal hypoparathyroidism, neonatal hyperparathyroidism, hypophosphatemia, or drug-induced hypercalcemia (thiazides).

**Table 105-4** Forms of Calcium Salts

FORM OF CALCIUM SALT	ELEMENTAL CALCIUM (mg/mL)
10% calcium gluconate	9.4
10% calcium chloride	27.2
Calcium glubionate syrup	23.6

Calcium gluconate administration is preferred over calcium chloride (may cause metabolic acidosis).

Derived from Rigo J, Mohamed WM, De Curtis M. Disorders of calcium, phosphorus and magnesium metabolism. In: Fanaroff AA, Martin RJ, eds. *Neonatal-Perinatal Medicine*. 9th ed. St Louis, MO: Mosby; 2011.

### Evaluation

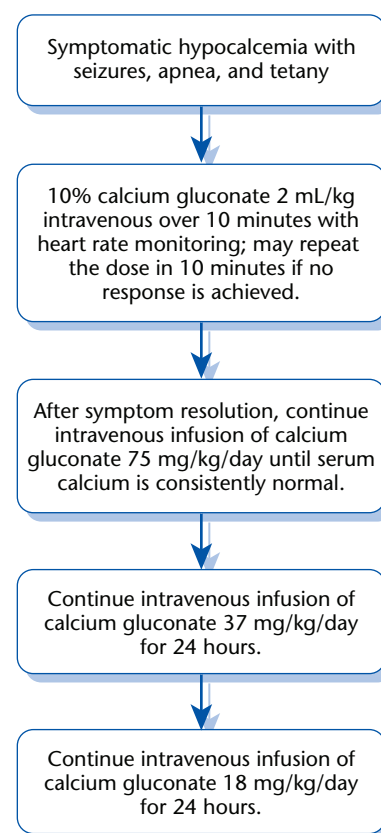

Newborns with hypercalcemia may be asymptomatic or have nonspecific signs, including poor feeding, constipation, polyuria, dehydration, decreased muscle tone, lethargy, and bradycardia. Long-term neonatal hypercalcemia may result in nephrocalcinosis.

### Management

The therapy of severe, symptomatic hypercalcemia in the acute phase should include intravenous fluid (normal saline) and furosemide administration to promote urinary calcium excretion, as well as removal of excessive calcium and vitamin D from the diet.

## MAGNESIUM METABOLISM IN THE FETUS AND METABOLIC ADAPTATION AT BIRTH

Most of maternal-fetal magnesium transfer occurs in the third trimester and involves active transport against a concentration gradient. Magnesium is found mostly in the skeleton and intracellular fluid, with only 1% present in the extracellular fluid, making assessment of stores difficult.

**Figure 105-3** Management of symptomatic hypocalcemia. (Derived from Rigo J, De Curtis M. Disorders of calcium, phosphorus and magnesium metabolism. In: Fanaroff AA, Martin RJ. *Neonatal-Perinatal Medicine*. 9th ed. St Louis, MO: Mosby; 2011.)

Magnesium is absorbed mainly in the small intestine; regulation of serum concentration is performed primarily by kidneys under PTH supervision. Increase in the serum magnesium will decrease PTH secretion and renal reabsorption, whereas decrease in magnesium concentration will lead to increased PTH release and decrease urinary excretion. Chronic magnesium deficiency, however, will reduce PTH secretion.

## HYPOMAGNESEMIA

### Definition

The normal serum magnesium value for the newborn is 0.66 to 1.15 mmol/L (1.6–2.8 mg/dL). Clinical symptoms usually do not develop until the serum magnesium level falls to less than 0.49 mmol/L (1.2 mg/dL). Measurement of active, ionized magnesium is usually not available; only total magnesium levels are routinely measured.

### Etiology

Table 105-5 summarizes the most common causes of neonatal hypomagnesemia.

### Evaluation

Hypomagnesemia in the neonatal period is usually transient and asymptomatic. However, in severe cases, hypomagnesemia can cause irritability, tremor, hyperexcitability, and intractable hypocalcemic seizures that are unresponsive to calcium and anticonvulsant therapy. Electrocardiographic data may show a prolonged QT interval.

Hypocalcemia can be explained by magnesium depletion and resulting hypoparathyroidism.

### Management

Management of hypomagnesemia consists of magnesium salt administration. The usual neonatal dose is 50% magnesium sulfate, 0.05 to 0.1 mL/kg (2.5–5 mg/kg of elemental magnesium) administered intramuscularly or by slow intravenous infusion over 15 to 20 minutes. The dose may be

repeated every 12 hours and eventually adjusted to oral preparations.

## HYPERMAGNESEMIA

### Definition

Hypermagnesemia is defined as a serum magnesium level higher than 1.15 mmol/L (2.8 mg/dL). Hypermagnesemia does not cause hypocalcemia in the neonatal period despite PTH suppression, possibly as a result of magnesium facilitating the bony release of calcium.

### Etiology

Hypermagnesemia in the neonatal period is always an iatrogenic event, commonly related to maternal magnesium sulfate administration for seizure prevention in preeclampsia or for tocolysis. Neonatal levels do not reach problematic values and return to normal within a few days as a result of urine excretion. Less common sources of excessive magnesium are magnesium-containing antacids or excessive magnesium in parenteral nutrition.

### Evaluation

The most common clinical manifestation of hypermagnesemia is hypotonia and depression at birth secondary to maternal administration of magnesium sulfate during obstetric management. Neurologic and respiratory depression may be evident on observation and examination.

### Management

Usual management consists of supportive treatment, including optimal hydration. Respiratory support may be required in extreme cases. With unusually severe central nervous system depression, exchange blood transfusion may be indicated to lower the serum magnesium level.

## TOOLS FOR PRACTICE

### Engaging Patient and Family

**Table 105-5**

**Differential Diagnosis of Neonatal Hypomagnesemia**

CAUSE	MECHANISM
Maternal diabetes	Maternal urinary losses of magnesium leading to neonatal magnesium depletion; blunted response to parathyroid hormone
Intrauterine growth restriction	Poor maternal supply or placental transfer
Hypoparathyroidism	Increased urinary losses
Malabsorption syndromes	Poor supply
Renal tubular defects: congenital or acquired (hypoxic ischemic syndrome, nephrotoxicity) or genetic defects of renal magnesium handling	Increased urinary losses
Defects of intestinal magnesium transport	Decreased absorption
Citrated blood transfusion	Complexing of citrate with ionized magnesium

## Chapter 106

# SPECIFIC CONGENITAL METABOLIC DISEASES

Angel Rios, MD; Darius J. Adams, MD

When evaluating a neonate the challenge that confronts the physician is to determine if a medical problem is a transient phenomenon that can be easily treated or if the problem will evolve into a life-threatening condition. Neonates often exhibit nonspecific signs and symptoms that may be indicative of an array of disorders, including sepsis, delayed transition, congenital cardiac disease, endocrine disturbances, and inborn errors of metabolism.

Newborns with metabolic disease are typically healthy and asymptomatic at birth. In utero the fetus is protected by the placenta, which is responsible for removing metabolites and transferring substrates to meet fetal energy needs. Once the fetal nutrient supply is withdrawn with clamping of the umbilical cord at delivery the newborn must activate physiological mechanisms to support metabolism, remove all toxic metabolites, and maintain an endogenous energy supply. Although inborn errors of metabolism are individually rare—for example, the incidence of medium-chain acyl-CoA dehydrogenase deficiency is 1 in 10,000—collectively inborn errors of metabolism have an incidence of 1 in 800 to 1,000. Clinical suspicion should be aroused in an infant who initially seems well and then progressively deteriorates despite appropriate therapy of the presenting clinical signs. The onset of symptoms caused by an inborn error of metabolism may range from a few hours after birth to several weeks of age, depending on the underlying disorder.

## EVALUATING THE NEWBORN

### Initial Approach

A complete family history is a crucial and integral part of the initial evaluation. Key items to include in the history are listed in Box 106-1. The initial assessment must also include a thorough physical examination and review of the pregnancy history. Maternal prenatal history can be useful in diagnosing inborn errors of metabolism. A newborn with a fatty acid oxidation disorder can predispose the mother to developing acute fatty liver of pregnancy and HELLP syndrome (preeclampsia with hemolysis, elevated liver enzymes, and low platelet count).

### Physical Examination

A thorough physical examination can provide helpful clues in identifying the correct diagnosis. Table 106-1 lists some of the common physical findings associated with specific metabolic and endocrine disorders. Some of the disorders listed do not cause acute illness in the newborn period, but the described physical findings are present from birth, such as the coarse facies in a newborn with galactosialidosis. The presence of atypical

HELLP, Hemolysis, elevated liver function tests, and low platelets.

**Table 106-1** Physical Findings Associated With Metabolic and Endocrine Disorders in the Newborn Period

FINDING	PROBLEM	DISORDER
Odor	Maple Syrup	Maple syrup urine disease
	Sweaty feet	Isovaleric acidemia
		Glutaric acid type II
	Musty	Phenylketonuria
	Cat urine	Multiple carboxylase deficiency
General appearance	Cabbage	Tyrosinemia
	Mid-line defects	Smith-Lemli-Opitz syndrome
Dysmorphism	Coarse facies	Galactosialidosis
		Sialidosis
		Mucopolysaccharidosis type VII
		G <sub>M1</sub> gangliosidosis
Head	Macrocephaly	Glutaric acidemia type I
	Microcephaly	Canavan disease
	Alopecia	Cobalamin disease type C
		Multiple carboxylase deficiency
Eye	Cataracts	Galactosemia, Zellweger syndrome
	Dislocated lens	Homocystinuria
Heart	Cardiomyopathy	Electron transport-chain disorders
		Disorders of fatty acid oxidation
		Glycogen storage disease type III
		Glycogen storage disease type IV (occasional)
		Electron transport-chain disorders
Visceromegaly	Hepatomegaly	Glycogen storage disease, Wilson disease
		Galactosemia, $\alpha_1$ -antitrypsin
		Disorders of fatty acid oxidation
	Hepatosplenomegaly	Lysosomal storage disorders
Neurologic	Hypotonia	Electron transport chain disorders
	Seizures	Medium-chain, acyl-coenzyme A dehydrogenase deficiency
	Lethargy	Maple syrup urine disease, nonketotic hyperglycinemia
	Coma	Urea cycle defects
Genitourinary	Microphallus	Smith-Lemli-Opitz syndrome

Left-hand side of A shows concentration in the fetus during the last trimester (data from 15 fresh still-births and 32 babies <4 hr old); right-hand side shows the changes after birth in babies of >37 weeks' gestation (data from 40 babies). Vertical lines indicate S.E. of the means

○ Babies of normal birth weight for the period of gestation

× Individual babies of low birth weight for the period of gestation

Insert B compares the changes after birth in babies of >37 weeks' gestation (○) with those born at 30–37 weeks (◐) and <30 weeks (●); total number of infants, 188

physical findings should alert the physician to potential problems.

## HYPOGLYCEMIA IN NEWBORNS

Hypoglycemia is among the more common signs in newborns. The incidence of hypoglycemia in healthy newborn infants is estimated to be between 5% and 15%. Prenatally, glucose is an important substrate because it serves as the primary fuel source for both the placenta and fetus. Glucose is responsible for supplying approximately 80% of fetal energy requirements. Because of the absence of gluconeogenesis in the fetus, it must rely on maternal glucose. The importance of maternally transported glucose is exemplified in a study revealing that over 95% of fetal plasma glucose was derived from maternal plasma. In addition, 40% of the transported glucose in the fetus is either converted to glycogen in the liver and muscle or to lipid for storage. Liver glycogen storage increases throughout gestation, with the major contribution occurring during the third trimester. Figure 106-1 reveals the changes in fetal liver glycogen as shown by Shelley and Nelligan: fetal liver glycogen rises dramatically

after 36 weeks' gestation. By term, the liver glycogen stores are 2 to 3 times the adult levels. Postnatally, glycogenolysis is critical with glycogen levels decreasing rapidly over the first 24 hours of life.

The human placenta regulates the transfer of glucose to the fetus by facilitated diffusion. Glucose transport is achieved by the activity of the facilitated diffusion glucose transporter (GLUT) protein family. Table 106-2 lists the various GLUT isoforms and their location and function. The driving force for glucose transport is the gradient from the higher maternal glucose concentration in comparison to the fetal glucose concentration. The 3 primary GLUT transporter isoforms found in the placenta are GLUT-1, GLUT-3, and GLUT-4. Figure 106-2 shows the distribution of GLUT transporter isoforms in the human placenta. GLUT-1 is the primary glucose transporter in the human placenta. The GLUT-1 transporter is asymmetrically distributed in the syncytiotrophoblast, where there is a 3-fold higher expression on the maternal-facing microvillous membrane compared to the fetal-facing basal membrane (see Figure 106-2). The decreased expression of GLUT-1 in the basal membrane has led

**Table 106-2** GLUT Facilitated-Diffusion Glucose Transporter Family

ISOFORM	LOCATION	FUNCTION(S)
GLUT1	Placenta, muscle, adipose tissue, brain, endothelium	Basal glucose transporter isoform for cellular metabolism and glucose transport
GLUT2	Pancreatic $\beta$ -cells, liver, small intestine, renal proximal tubule	High-capacity, low-affinity (high $K_m$ ) isoform. Acts as a glucose sensor and in transepithelial of glucose and fructose
GLUT3	Neural, small intestine	High-affinity (low $K_m$ ) isoform, possibly to act as a scavenger for cells with a high rate of glucose metabolism
GLUT4	Muscle, heart, adipose tissue	Insulin-responsive isoform; expressed only in insulin-responsive cells/tissues. Translocates to plasma membrane upon insulin stimulation
GLUT5	Small intestine, brain, muscle and adipose tissue	Fructose transporter
GLUT6	Ubiquitous	Pseudogene, nonfunctional

to the proposal that the basal membrane performs as the rate limiting step in transplacental glucose transfer from the mother to the fetus. GLUT-3 seems to be expressed in the vascular endothelium and has been recently discovered in the placental syncytial microvillous membrane. There is high expression of GLUT-3 early in pregnancy, decreasing as the fetus approaches term. This increase in GLUT-3 expression early in fetal life suggests higher glucose needs in fetal growth during early pregnancy. The distinct changes in the expression in GLUT-3 seem to be controlled by the placental production of CRH. GLUT-4 has only been identified in the stroma of the placental villous. The role of GLUT-4 is uncertain.

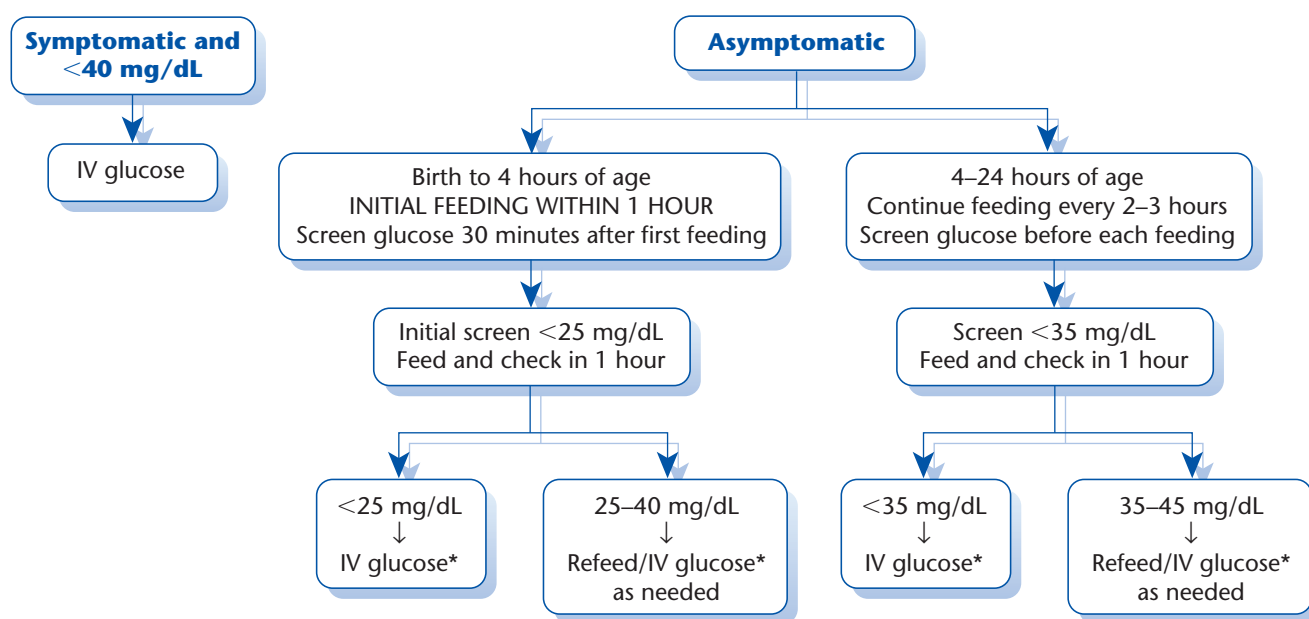

The fetal blood glucose level is approximately 70% of the maternal level. Hypoglycemia may be caused by many conditions that increase the infant's metabolic rate or may result from inadequate endogenous glycogen stores in infants born preterm or growth restricted. Box 106-2 lists signs and symptoms that may be present in the hypoglycemic newborn. There continues to be controversy about the degree of hypoglycemia that can cause neurologic damage. Although a number of studies using magnetic resonance imaging have described a wide spectrum of cerebral injury associated with hypoglycemia, such as bilateral loss of white/grey matter differentiation in the parietal occipital lobe, corticospinal tract injury, and damage to basal ganglia and thalamus, there are no evidence-based studies that directly associate neurologic damage with an absolute glucose concentration. Therefore, treatment of hypoglycemia remains to a great extent empiric. In 2011, the Committee on Fetus and Newborn of the American Academy of Pediatrics developed pragmatic screening and management guidelines for postnatal glucose homeostasis in "at-risk" newborn infants, a category including the late preterm (34<sup>0</sup>/<sub>7</sub> to 36<sup>6</sup>/<sub>7</sub> weeks' gestational age) and term small-for-gestational-age (SGA) infants, and infants of diabetic mothers (IDM)/large-for-gestational-age (LGA) infants. In a study enrolling 514 "high-risk" newborn infants, hypoglycemia occurred in 51% infants (hypoglycemia defined as a glucose level of <46 mg/dl [ $<2.6$  mmol/L]) with 19% developing severe hypoglycemia (defined as

Glucose transporters in the human placenta. *Placenta* 2000;21[1]: 14–22, with permission from Elsevier.)

### BOX 106-2 Signs and Symptoms of Hypoglycemia

Cyanotic spells	Tremors
Apnea	Poor feeding
Respiratory distress	Hypotonia
Temperature instability	Tachypnea
Seizures	Tachycardia
Lethargy	Bradycardia
Irritability	Vomiting
Coma	

Target glucose screen  $\geq 45$  mg/dL before routine feedings

\*Glucose dose = 200 mg/kg (dextrose 10% at 2 mL/kg) and/or IV infusion at 5–8 mg/kg per min (80–100 mL/kg/day). Achieve plasma glucose level of 40–50 mg/dL.

Symptoms of hypoglycemia include: irritability, tremors, jitteriness, exaggerated Moro reflex, high-pitched cry, seizures, lethargy, floppiness, cyanosis, apnea, poor feeding.

**Figure 106-3** Screening for and management of postnatal glucose homeostasis in late-preterm (LPT 34 $\frac{0}{7}$ –36 $\frac{6}{7}$  weeks) and term small-for-gestational age (SGA) infants and infants who were born to mothers with diabetes (IDM)/large-for-gestational-age (LGA) infants. LPT and SGA (screen 0–24 hours), IDM and LGA  $\geq 34$  weeks (screen 0–12 hours). IV indicates intravenous. (From American Academy of Pediatrics Committee on Fetus and Newborn. Postnatal glucose homeostasis in late-preterm and term infants. *Pediatrics*. 2011;127[3]:575–579.)

a glucose level of  $<40$  mg/dL). Eighty-one percent of infants developed hypoglycemia within the first 24 hours of life with a mean duration of 1.4 hours. This study reveals the vulnerability of developing hypoglycemia in this population of infants and the importance of close monitoring during the first 24 hours of life. Figure 106-3 describes the management approach in this high-risk population.

The physician should consider inborn errors of metabolism and endocrine abnormalities in the differential diagnosis of a newborn whose symptoms persist despite appropriate therapy. Prompt diagnosis and initiation of appropriate therapy are essential to prevent death and permanent neurologic damage.

In the initial hours after delivery the typical newborn does not have fully active gluconeogenic function and is consequently unable to use alanine, lactate, and glycerol efficiently for endogenous hepatic glucose production. Delay in the expression of phosphoenolpyruvate

carboxykinase (PEPCK), the rate-limiting step in the gluconeogenesis pathway, increases the susceptibility of the neonate to developing hypoglycemia. By 24 hours of age, PEPCK reaches adult values. Therefore, early, serial preprandial glucose monitoring in conjunction with the initiation of early feedings is important in the care of a newborn with risk factors for hypoglycemia. Other causes of hypoglycemia must be considered in neonates with persistent hypoglycemia beyond 24 hours of age, including severe refractory hypoglycemia and hypoglycemia not responding to enteral feeds, as well as newborns with persistent clinical signs as detailed in Box 106-2. Box 106-3 provides a list of factors that may contribute to neonatal hypoglycemia. Hypoglycemia caused by congenital hyperinsulinism occurs during the first few days of life, but cases occurring later in infancy and childhood have been reported. Hypoglycemia that occurs because of congenital hyperinsulinism is severe and persistent, requiring

**BOX 106-3 Etiologic Factors Contributing to Neonatal Hypoglycemia****PRENATAL CAUSES**

- Maternal diabetes
- Maternal drug administration
- Beta-sympathomimetics
- Intrapartum intravenous dextrose bolus
- Oral hypoglycemics
- Propylthiouracil
- Pregnancy-induced hypertension

**EXCESS UTILIZATION**

- Hyperinsulinism
- IDM
- LGA
- SGA
- Erythroblastosis
- Increased energy expenditure
- RDS
- Sepsis
- Seizures
- Drug withdrawals
- Hypothermia
- Increased work of breathing
- Inborn errors of metabolism
- Hypoxemia
- Ischemia
- Shock

- Hemorrhage
- Postexchange transfusion
- Hyperviscosity, polycythemia

**INADEQUATE PRODUCTION OR SUBSTRATE DELIVERY**

- Inadequate delivery of calories
- Delayed enteral or parenteral nutrition
- Transient developmental immaturity of critical metabolic pathways, reducing endogenous production of glucose or other substrates
- Endocrine disorders:
  - Hypothyroidism
  - Hypothalamic
  - Pituitary
- Abrupt cessation of hypertonic parenteral glucose
- Discordant twins
- Cerebral hemorrhage
- Perinatal asphyxia
- SGA
- Glucose transporter deficiency
- Suppressed gluconeogenesis, glycogenolysis, lipolysis, proteolysis and ketogenesis secondary elevated insulin levels (hyperinsulinism).

**IATROGENIC CAUSES**

- Malposition of umbilical catheter
- Cold stress

IDM, Infant of diabetic mother; LGA, large for gestational age; RDS, respiratory distress syndrome; SGA, small for gestational age. Modified from Cornblath M, Ichord R. Hypoglycemia in the neonate. *Semin Perinatol*. 2000;24(2):136–149, with permission from Elsevier.

**Table 106-3 Initial Management Steps to Consider to Treat Persistent, Severe Hypoglycemia**

Step 1	Obtain labs: glucose, growth hormone, insulin, and cortisol levels
Step 2	Give D10 2 ml/kg (200 mg/kg) IV push Increase IV infusion 10%–15%
Step 3	Repeat blood glucose
Repeat step 2 if hypoglycemia persists. Consider additional medical management if glucose infusion rate >15 mg/kg/min.	

large glucose infusion rates to maintain euglycemia. Glucose infusion rates greater than 15 mg/kg/min are often necessary. Endogenous hepatic glucose production and utilization rate in the healthy newborn is 4 to 6 mg/kg/min. Euglycemia can be maintained in the otherwise healthy newborn with a glucose infusion rate of 5 to 8 mg/kg/min. This circumstance is in stark contrast to the hyperinsulinism exhibited by infants of diabetic mothers and those who are growth restricted or experience perinatal asphyxia. The hyperinsulinism present in these conditions is transient. Transient

hyperinsulinism can also occur without any predisposing factors. Table 106-3 describes the recommended management steps if the hypoglycemic episode is refractory to initial treatment. Additional medical management may be required for glucose infusion rates >15 mg/kg/min.

The following formula can be used to determine the glucose infusion rate (GIR):

$$\text{GIR (mg/kg/min)} = \frac{\% \text{ dextrose} \times \text{infusion rate (ml/hr)}}{6 \times \text{weight (kg)}}$$

## APPROACH TO THE INFANT WITH PERSISTENT HYPOGLYCEMIA

Ascertaining the cause of persistent hypoglycemia requires an understanding of the adaptive processes involved in the response to hypoglycemia and application of a systematic approach in identifying any underlying metabolic problems.

Physicians often initially suspect sepsis in the infant who is hypoglycemic and seems ill; metabolic disorders may not be considered until the infant exhibits continued deterioration despite standard therapeutic measures or when laboratory results fail to support or confirm a diagnosis of infection. Furthermore, metabolic disorders may cause other systemic manifestations. An infant affected by galactosemia may develop *Escherichia coli* sepsis, whereas an infant with glycogen storage disease type Ib (glucose-6-phosphatase translocase deficiency) or organic aciduria may exhibit neutropenia, thus mimicking sepsis in the newborn in face of a metabolic disorder. A metabolic or endocrine disorder should be suspected when altered consciousness or seizures occur in conjunction with profound hypoglycemia requiring greater than 15 mg/kg/min glucose infusion rates or if hypoglycemia is not responding to standard therapy.

Hypoglycemia can occur at distinct times depending on the disorder and may also occur preprandially, postprandially, or during a period of fasting. The timing of the hypoglycemic episode can be a helpful clue to its underlying cause. Five processes are responsible for maintaining normal blood glucose levels during periods of fasting in the healthy newborn infant:

1. Glycogenolysis
2. Gluconeogenesis
3. Adipose tissue lipolysis
4. Fatty acid oxidation (to synthesize glucose and ketone bodies)
5. Endocrine system capable of integrating and modulating these first 4 processes during periods of fasting

Sufficient endogenous gluconeogenic substrates (amino acids, glycerol, and lactate) are required for these metabolic reactions. Glycogenolysis, gluconeogenesis, adipose tissue lipolysis, and fatty acid oxidation are temporally related. Figure 106-4 illustrates the relationships of these processes when prolonged starvation occurs during the newborn period. Once the endogenous supply of glucose is exhausted, glycogenolysis (process 2) takes over, usually after 4 hours. Gluconeogenesis (process 3) is activated, achieving peak activity after 12 hours of starvation. Fatty acid oxidation (process 4) begins to peak after 14 hours. Figure 106-5 reveals the relationship of the various processes after 24 hours.

Infants with progressive clinical deterioration and a high clinical suspicion of inborn error of metabolism require prompt detection and intervention.

### Process 1: Gastrointestinal Absorption of Glucose

Glucose becomes available from gastrointestinal nutrient absorption immediately after feeding. Breast-feeding infants have a greater capacity to generate ketone bodies compared with formula-feeding neonates, suggesting that human milk augments ketogenesis in human neonates through as yet undescribed

**Figure 106-4** Glycogenolysis, gluconeogenesis, lipolysis, and fatty acid oxidation are temporally related. (Adapted from Ruderman NB, Aoki TT, Cahill GF Jr. *Gluconeogenesis and its disorders in man*. In: Hanson RW, Mehlman MA, eds. *Gluconeogenesis, Its Regulations in Mamalian Species*. New York: John Wiley & Sons, Inc; 1976: 518, with permission.)

**Figure 106-5** The relationship of glycogenolysis, gluconeogenesis, and fatty acid oxidation after 24 hours and beyond.

pathways. Insulin and glucose levels are elevated, and glucagon is depressed as intestinal absorption of glucose takes place. Hypoglycemia occurring during this phase suggests hyperinsulinism. Excessive insulin secretion in response to an enteral feeding induces a hypoglycemic response. Consequently, hypoglycemia that is caused by hyperinsulinism is typically responsive to administration of glucagon and octreotide.

Figure 106-6 depicts how hepatic glycogenolysis preserves blood glucose homeostasis during process 1 (early fasting), a time in which gastrointestinal absorption of glucose is predominant.

Causes of neonatal hyperinsulinism are listed in Box 106-4. Although the underlying cause of hyperinsulinism varies, the basic problem is increased glucose

**Figure 106-6** Metabolic interrelationships of major tissues in early fasting state. (Adapted from Devlin TM, ed. Textbook of Biochemistry With Clinical Correlations. 7th ed. New York: John Wiley & Sons; 2011: 843. Reprinted by permission.)

#### BOX 106-4 Causes of Neonatal Hyperinsulinism

- Infant of diabetic mother
- Intrauterine growth restriction
- Perinatal asphyxia
- Congenital hyperinsulinism
- Beckwith-Wiedemann syndrome
- Hypopituitarism
- Rh isoimmunization

utilization resulting from excessive insulin secretion or, in the case of Beckwith-Wiedemann syndrome, excess tissue production of insulin-like growth factor-II. Some disorders have a genetic basis (Beckwith-Wiedemann syndrome, congenital hyperinsulinism), whereas others can be associated with adverse intrauterine events (intrauterine growth restriction, perinatal asphyxia). Infants of diabetic mothers, intrauterine growth-restricted infants, and infants who experience perinatal asphyxia typically receive parenteral glucose

infusions during the initial stabilization period. Congenital hyperinsulinism, Beckwith-Wiedemann syndrome, and hypopituitarism require more extensive treatment as an adjunct to high concentrations of infused glucose.

#### Infant of Diabetic Mother

Infants born to mothers with diabetes risk developing hypoglycemia as a result of fetal responses to chronic intrauterine hyperglycemia. As noted previously, glucose is transported from the maternal circulation to the fetus by facilitated diffusion. This process is driven by the concentration gradient between the maternal and fetal blood glucose. At birth the newborn's insulin secretion remains elevated while the maternal source of glucose abruptly ceases. The greatest risk for developing hypoglycemia in the IDM is in the first few hours after birth and may continue through the first 48 hours of life. The increased release of insulin results from an increased sensitivity of the  $\beta$ -cell to stimulation. An IDM will secrete more insulin in response to a given amount of glucose than an infant born to a mother without diabetes. The increase in  $\beta$ -cell sensitivity progressively diminishes over the first 7 to 10 days of age. An IDM can be macrosomic with significant adiposity because increased insulin levels in utero stimulate fetal growth. Therefore, all LGA infants should be monitored for hypoglycemia resulting from hyperinsulinism.

#### Congenital Hyperinsulinism

**PATHOPHYSIOLOGIC FEATURES.** Congenital hyperinsulinism is the most common cause of persistent hypoglycemia occurring in the neonatal period. The incidence varies from 1 in 3,000 live births in parts of the Middle East to 1 in 40,000 live births in parts of Europe. Congenital hyperinsulinism is characterized by recurrent and persistent fasting hypoglycemia caused by dysregulation of insulin secretion. Nesidioblastosis, which is a diffuse proliferation of pancreatic islet cells, was thought to be the cause of congenital hyperinsulinism. However, nesidioblastosis is a common pancreatic finding in normoglycemic newborns. The most common cause of congenital hyperinsulinism responsible for 40% to 45% of cases involves the ABCC8 and the KCNJ11 genes that are located on chromosome 11 and encode the SUR1 and KIR6.2 proteins. These proteins are subunits of the  $\beta$ -cell responsible for the adenosine triphosphate-sensitive potassium ( $K^+_{ATP}$ ) channels. In 5% to 10% of cases congenital hyperinsulinism occurs as a result of enzymatic or transcription anomalies secondary to gene mutations. The cause of the remaining cases remains unknown. Table 106-4 lists the genes responsible for congenital hyperinsulinism. The inheritance of congenital hyperinsulinism can occur with autosomal-recessive or -dominant mutations of the ABCC8 or KCNJ11 genes. Some infants with congenital hyperinsulinism inherit it as an autosomal-recessive trait. Figure 106-7 demonstrates the actions of the SUR1 and KIR6.2 in the pancreatic ( $\beta$ -cell secretion). The  $K^+_{ATP}$  channels are octameric complexes comprising 2 types of subunits—4 regulatory SUR1 (sulphonylurea receptors) surrounding 4 KIR6.2 (pore-forming inwardly rectifying potassium channels); see Figure 106-8. When there is a normal increase in blood glucose that results in an increase in intracellular ATP, the increase in

intracellular ATP inhibits the potassium efflux through the  $K^+_{ATP}$  channels. The closure of the potassium channels depolarizes the plasma membrane, which activates calcium channels increasing the intracellular calcium, resulting in the release of insulin via exocytosis. Each  $K^+_{ATP}$  channel contains at least 2 of these proteins. These mutations impair the function of the  $K^+_{ATP}$  channels and are inherited in an autosomal-recessive manner.

Hyperinsulinism-hyperammonemia syndrome is an autosomal-dominant condition that causes hypoglycemia. A serum ammonia level should be added to the diagnostic evaluation to determine this possibility. Hyperinsulinism-hyperammonemia syndrome is caused by mutations in the glutamate dehydrogenase gene.

**LABORATORY EVALUATION.** Laboratory findings include hyperinsulinemia in the presence of symptomatic hypoglycemia. Table 106-5 lists the blood and urine samples required when evaluating for persistent refractory hypoglycemia. These laboratory evaluations should be obtained prior to medical treatment of hypoglycemia. The unrestricted insulin release inhibits counterregulatory mechanisms. This inhibition will affect ketone body synthesis and lipolysis, resulting in a decrease in blood ketones and fatty acids. Gluconeogenesis is also inhibited. Newborns with congenital hyperinsulinism are at risk for brain damage resulting from hypoglycemia and lack of alternate fuels for brain metabolism. Serum cortisol response is blunted, and glucocorticoid administration does not correct the hypoglycemia. A definitive diagnosis of hyperinsulinism is made based on insulin and cortisol levels obtained during the acute hypoglycemic episode, but may be difficult in mild cases. The physician needs a high index of suspicion; otherwise, the diagnosis can easily be missed.

**TREATMENT STRATEGIES.** Adequate carbohydrate intake can be provided with intravenous glucose or enteral feeds, as described, and is critical to prevent brain injury. Correction of hypoglycemia may require glucose infusion rates greater than 15 mg/kg/min. A central line is required when administering glucose at concentrations greater than 12.5% dextrose because higher concentrations of intravenous glucose are particularly caustic to blood vessels. Table 106-6 provides a list of medications that may be used in the treatment of hypoglycemia. Surgery involving partial pancreatectomy or resection of localized adenomas is reserved for infants who fail to respond to medical management. Percutaneous transhepatic pancreatic venous blood sampling may be used to identify these “hot spots.”

Compared to the more invasive pancreatic blood sampling mentioned above, the use of fluorine-18-L-dihydroxyphenylalanine ( $^{18}F$ -Dopa PET) is gaining more popularity because it is less invasive and requires less ionizing radiation.  $^{18}F$ -Dopa PET takes advantage of the incorporation of DOPA by the  $\beta$ -cells, which is converted into dopamine by aromatic L-amino acid decarboxylase. In one study, the  $^{18}F$ -Dopa PET scan was shown to be useful in defining the extent of the lesion in two-thirds of cases; the authors recommend the need for intraoperative histologic confirmation.

**Diazoxide and Chlorothiazide.** Diazoxide and chlorothiazide together are the drugs of choice. Diazoxide is a ligand of the  $K^+_{ATP}$  channel, which binds to SUR1 and, in the presence of intracellular nucleotides, opens the channels. Chlorothiazide acts on the  $K^+_{ATP}$  channels but is also used to overcome the fluid retention caused by diazoxide.

**Glucagon.** Glucagon may be used in the acute management of hypoglycemia. Its onset of action is

**Table 106-5** Blood and Urine Samples Required During Hypoglycemia

BLOOD SPECIMEN	REQUIRED SAMPLE	NORMAL VALUES
Insulin	Serum	3–20 mcU/mL
Growth hormone	Heparinized serum/plasma	5–53 ng/mL
Cortisol	Heparinized serum/plasma	1–24 mcg/dL
Glucose	Serum	40–60 mg/dL
<b>ELECTROLYTES AND LIVER FUNCTION TEST RESULTS</b>		
Blood gas	Heparinized whole blood	7.26–7.45 pH
Ketones	Whole blood	0.1–1.5 mmol/L
Lactate	Whole blood	1.1–2.3 mmol/L
Ammonia	Whole blood	21–95 mmol/L
Free fatty acids	Whole blood	0.5–1.6 mmol/L
Uric acid	Serum	1.7–5.8 mg/dL

Reducing substances	—	Negative

10 to 15 minutes, and its effect is transient. Glucagon should only be used as an acute therapy in infants with adequate glycogen stores. Glucagon is not appropriate for use in small-for-gestational-age and low-birth-weight infants. Subcutaneous or intravenous administration of glucagon in a dose of 0.5 to 1.0 mg will stimulate mobilization of endogenous glycogen stores and result in an increase in blood glucose greater than 30 mg/dL.

**Octreotide.** Octreotide is an analogue of somatostatin that can be used in the acute and chronic treatment of hypoglycemia. As a somatostatin analogue, octreotide has an inhibitory effect on various hormones, including growth hormone (GH), thyroid-stimulating hormone (TSH), and adrenocorticotrophic hormone (ACTH). Octreotide is also used in the treatment of congenital hyperinsulinism. Octreotide's mechanisms of action include alteration in  $\beta$ -cell intracellular translocation of calcium and inhibition of insulin-containing granule exocytosis. Octreotide can decrease gallbladder contractility and bile secretion leading to hepatic dysfunction, steatorrhea, cholestasis, and cholelithiasis. Octreotide can also decrease splanchnic blood flow, potentially increasing the risk of necrotizing enterocolitis.

### Beckwith-Wiedemann Syndrome

Beckwith-Wiedemann syndrome is an imprinting disorder occurring in approximately 1 in 14,000 newborns. Approximately 85% of cases are sporadic,

inheritance is complex, and a familial autosomal-dominant form with a variable phenotype has been described. The critical chromosomal region responsible for Beckwith-Wiedemann syndrome is located at 11p15.5. Beckwith-Wiedemann syndrome occurs when paternal uniparental disomy is present (an imprinting defect in which the maternal allele is not expressed), with microdeletions involving the critical region, with contiguous gene duplications in the 11p15 region, or with *CDKN1C* mutations. Characteristic findings include macrosomia (defined as birth weight >4,000 g), an abdominal wall defect, and macroglossia. Other features include hemihypertrophy, indentations on the posterior rim of the ear's helix, and linear creases of the earlobe. Treatment of the hypoglycemia is as described previously, and the hypoglycemia tends to resolve over time. Long-term management includes monitoring alpha-fetoprotein levels and abdominal sonography to monitor for tumor development, that is, Wilms tumors. Figure 106-8 depicts the metabolic pathways involved in maintaining euglycemia.

In the following sections, specific metabolic pathways and their involvement in maintaining euglycemia are examined.

### Process 2: Glycogenolysis—Postabsorptive and Early Catabolism

Glycogenolysis occurs when glycogen stored in the liver is broken down after completion of intestinal carbohydrate absorption, approximately 3 to 4 hours

**Table 106-6** Additional Medical Management for Hypoglycemia Requiring a Glucose Infusion (>15–20 mg/kg/min)

MEDICATION	MECHANISM OF ACTION	ROUTE OF ADMINISTRATION	DOSE	SIDE EFFECTS
Glucagon	Increased glycogenolysis and gluconeogenesis	SC, IV, IM <b>Use only in acute management.</b>	0.025–0.3 mg/kg/dose repeat 20 min as needed (max dose 1 mg)	Nausea, vomiting Do not use in SGA or low-birth-weight infants.
Diazoxide	K <sup>+</sup> <sub>ATP</sub> channel agonist decreasing insulin secretion	IV, PO	2–5 mg/kg IV push 2–105 mg/kg every 8–12 hr	Hyponatremia and fluid retention, hypertrichosis, hypotension
Chlorothiazide	Unknown	PO IV not recommended in infants and children.	6 mo–2 yr: 10–20 mg/kg divided twice daily (max. 375 mg) 2–12 yr: 1 g divided twice daily >12 yr: 30–60 mg/kg divided two to three times daily (max. 2 g)	Hypotension, alopecia, photosensitivity, hyperuricemia
Octreotide	Inhibits insulin and GH	SC, IV	Start 2–10 mcg/kg/day every 6–8 hours. Increase up to 40 mcg/kg/day every 4–8 hours	Tachyphylaxis, diarrhea, constipation
Hydrocortisone	Decreased peripheral glucose utilization	IV, IM	5 mg/kg every 12 hours	Immunosuppression, growth delay, gastric irritation

GH, growth hormone; IM, intramuscular; IV, intravenous; SC, subcutaneous; SGA, small for gestational age; PO, oral.

postprandially. Liver glycogen stores are 50 to 75 g/kg of liver. During glycogenolysis, glucose-6-phosphate (G-6-P) is produced, releasing glucose by the action of glucose-6-phosphatase. Insulin levels return to basal levels, and increasing glucagon and epinephrine levels augment glycogenolysis. The brain, red blood cells, and renal medulla use glucose exclusively.

Hypoglycemia occurring during this phase is suggestive of an abnormality in glycogenesis. Muscle glycogen cannot be used by other tissues during this phase because muscle cells lack glucose-6-phosphatase. Box 106-5 lists the disorders of glycogenesis.

### **Glycogen Storage Disease Type I**

Glycogen storage disease type I (GSD I) has been classified as a disorder of gluconeogenesis because the enzyme glucose-6-phosphatase catalyzes the final common step in glycogenolysis and gluconeogenesis. The most common abnormalities found in GSD types Ia and Ib are hypoglycemia, lactic acidosis, hyperlipidemia, and hyperuricemia. GSD type Ia is secondary to a deficiency of glucose-6-phosphatase, whereas GSD Ib is caused by mutations in the glucose-6-phosphate translocase gene, responsible for the microsomal transport of glucose-6-phosphatase. The common end result of GSD types Ia and Ib is blockage of glucose release from the liver. The gene for glucose-6-phosphatase is located on chromosome 17q21. The gene for the glucose-6-phosphate transporter gene is located on chromosome 11q23. Inheritance is autosomal recessive for both forms of GSD. These enzymatic defects result in an excessive accumulation of both glycogen and fat in the liver. These 2 types of GSD are not clinically discernable; the major difference is that GSD Ib has an increased risk of infection and immunologic abnormalities. GSD Ib is associated with a decreased number of neutrophils and defective neutrophil and monocyte function, which increases the risk for infections. This circumstance is another example of a metabolic disease with an increased susceptibility to bacterial infection, thereby potentially masking the metabolic disorder. Definitive diagnosis is achieved by performing a liver biopsy along with enzyme analysis or by DNA analysis. As encountered in all disorders of glycogenesis, hypoglycemia becomes evident when exogenous glucose sources are depleted. Glucose-6-phosphatase has the combined effect of blocking glucose release from both the glycogenolytic and gluconeogenic pathways.

#### **BOX 106-5 Disorders of Glycogenesis**

- Glycogen storage disease type Ia (glucose-6-phosphatase deficiency, Von Gierke disease) and type Ib (glucose-6-phosphate translocase deficiency)
- Glycogen storage disease type III (debranching-enzyme deficiency)
- Glycogen synthase deficiency
- Mitochondrial respiratory-chain disorders

The goal of treatment is to prevent hypoglycemia-induced brain damage. Therapy consists of frequent feedings, initially by continuous nasogastric feedings and then by feeding uncooked cornstarch, particularly overnight. Uncooked cornstarch has the advantage of having a more protracted release of glucose than is available from cooked cornstarch; however, cornstarch use is limited to children older than 1 year. The dose of uncooked starch is 1.6 g/kg every 4 hours in patients between 1 and 2 years of age. Children unresponsive to cornstarch can be given continuous nasogastric infusion of glucose to prevent hypoglycemia. Fructose and galactose are restricted from the diet. Galactose and fructose must be converted to glucose-6-phosphate or to fructose-6-phosphate, respectively, before forming glucose. Because glucose-6-phosphatase is deficient, glucose-6-phosphate enters glycolysis, which results in a dramatic increase in lactate levels. Allopurinol is given to control the uric acid levels and prevent uric acid crystal accumulation. For patients with GSD type Ib, granulocyte colony-stimulating factor is used to prevent neutropenia and to decrease the severity of bacterial infections. Long-term outcomes in patients with GSD types Ia and Ib can be good if diagnosis occurs early and treatment is started promptly.

### **Glycogen Storage Disease Type III (Debranching-Enzyme Deficiency)**

GSD type III results from a deficiency of the debranching enzyme, amylo-1,6-glucosidase. The inheritance pattern is autosomal recessive. The gene for this debranching enzyme is located on chromosome 1p21. Debranching-enzyme deficiency results in an inability to degrade stored glycogen, thereby impairing the release of glucose from glycogen. Glucose production from gluconeogenesis remains unaffected. Some of the clinical features of GSD III are similar to those of GSD I. Hepatomegaly is present at birth as a result of glycogen accumulation, and improves gradually during the course of childhood. Although this disorder usually occurs in infancy, severe hypoglycemia can occur at birth and steadily improves with advancing age; thus GSD III differs dramatically from GSD I in this respect. Approximately 85% of patients exhibit liver and muscle (cardiac and skeletal) involvement (type IIIa). Myopathy is the major chronic morbidity associated with GSD type IIIa, while 15% of patients with GSD type IIIb have liver involvement without any associated muscle disturbance. GSD IIIa and IIIb are allelic disorders. Patients with IIIa have enzyme deficiency in both the liver and muscle, while patients with IIIb have enzyme deficiency limited to the liver. In comparison with GSD type I, concentrations of lactate and uric acid are normal. Unlike with GSD type I, no dietary restriction of fructose and glucose is required in these patients.

### **Differences Between GSD Type I and GSD Type III**

After a glucose challenge, lactate and uric acid levels are normal in GSD type III. Alanine levels are lower in

GSD III compared with GSD I, given that individuals with GSD III have increased gluconeogenesis and lower lactate levels. Therefore, the hypoglycemia in GSD III is usually not as severe as in GSD I. A robust response to a glucagon challenge is seen in patients with GSD III compared to those with GSD I after a short fast; however, this more robust response will decrease as the length of the fast increases.

Definitive diagnosis is made by confirming deficiency of amylo-1,6-glucosidase in leukocytes or from a liver, muscle, or skin biopsy. Prenatal diagnosis has been accomplished by amniocyte or chorionic villus sampling using enzyme activity analysis or immunoblot analysis. In comparison with GSD I, treatment of GSD III is easier to implement.

### **Glycogen Synthase Deficiency**

Glycogen synthase deficiency is a rare disorder that results in decreased synthesis of glycogen leading to decreased glycogen stores. Glycogen synthase deficiency is not a GSD because no accumulation of glycogen occurs. Glycogen synthase deficiency leads to ketotic hypoglycemia. Blood levels of lactate and alanine are low and no hyperlipidemia is present. Unlike GSD I and III, glycogen synthase deficiency can be observed clinically with a liver that is normal or slightly enlarged because of the decreased glycogen synthesis. Glucagon response after fasting hypoglycemia is usually reduced or absent, although it may be present in some affected infants. A minimal or absent response to glucagon suggests the diagnosis. Individuals with this condition also exhibit hyperglycemia and hyperlactatemia after feeding because of an inability to store excess glucose. Glycogen synthase is expressed only by the liver. The diagnosis is confirmed by liver enzymatic studies on a liver biopsy specimen.

### **Mitochondrial Respiratory-Chain Disorders**

Mitochondrial diseases involve the impairment of the oxidative phosphorylation (OXPHOS) system. The mitochondria's major goal is to provide the energy required for normal cellular function through the process of OXPHOS. The OXPHOS system consists of 5 multienzymatic complexes. These complexes are divided into 4 respiratory chain complexes (complex I, II, III, and IV) each existing independently in the mitochondrial inner membrane and ending at the adenosine triphosphate synthase (complex V) to form ATP, the molecule that supplies energy for cellular metabolism. Its synthesis is achieved by an electrochemical gradient. Any defect in the respiratory chain will affect mitochondrial respiration and energy production and cause neonatal decompensation consisting of clinical symptoms primarily involving organs with high energy demands. Respiratory-chain proteins are encoded by a large number of genes, resulting in several patterns of genetic inheritance that can cause mitochondrial disorders. Disorders of the respiratory chain can occur through spontaneous, autosomal-recessive, autosomal-dominant, X-linked, and maternally inherited mutations. Although these diseases can occur at virtually any age, the neonatal presentation can include hypoglycemia, apnea, seizures, lethargy, muscle atrophy, hypotonia, sideroblastic anemia,

lactic acidosis, coma, hepatomegaly with liver failure, and hypertrophic cardiomyopathies. Lactic acidosis is a common finding. Diagnosis is made by obtaining a muscle biopsy with mitochondrial enzyme analysis.

### **Process 3: Gluconeogenesis During Early or Intermediate Starvation**

Once hepatic glycogen stores are depleted, gluconeogenesis becomes the primary source for energy. Gluconeogenesis progressively replaces glycogen as the major source of glucose. Therefore, hypoglycemia during this phase suggests impaired gluconeogenesis. Gluconeogenesis typically begins after 12 to 16 hours of fasting once glycogen stores are depleted in the term infant. This process may occur more rapidly in preterm and stressed newborn infants. Gluconeogenesis uses amino acids, lactate, and glycerol to manufacture glucose. The most characteristic feature in newborns with defects of gluconeogenesis is hepatomegaly without evidence of liver insufficiency. Important substrates for gluconeogenesis are lactate, alanine, and oxaloacetate. A hallmark of the disorders of gluconeogenesis is elevation of alanine, pyruvate, and lactate levels. Both alanine and lactate are in equilibrium with pyruvate. Abnormalities in gluconeogenesis cause an increase in downstream metabolites such as pyruvate that causes elevations in lactate and alanine. During gluconeogenesis, the brain is not yet using ketone bodies significantly. Fatty acids used for lipolysis and glycerol production become essential when prolonged fasting occurs. Box 106-6 lists the disorders of gluconeogenesis.

### **Fructose-1,6-Diphosphatase Deficiency**

Fructose-1,6-diphosphatase deficiency is a disorder of gluconeogenesis rather than a defect in fructose metabolism. Fructose-1,6-diphosphatase deficiency is inherited in an autosomal-recessive manner. Newborns usually exhibit severe hypoglycemia and lactic acidosis during the first few days of life. These episodes are triggered by decreased oral intake. Clinical symptoms include apnea, tachycardia, hyperventilation, lethargy, and seizures. Fructose-1,6-diphosphatase deficiency has a direct effect on the formation of glucose involving gluconeogenic precursors. Hypoglycemia occurs because of the inability to make fructose-1-phosphate from fructose-1, 6-diphosphate. Fructose-1-phosphate is an important precursor to glucose formation. The enzyme deficiency results in a downstream increase in pyruvate, resulting in severe lactic acidosis. Laboratory analysis reveals increased levels of lactate, alanine, glycerol, and ketones. Definitive diagnosis is made by measuring fructose-1,6-diphosphatase activity in liver tissue. Because of the heterogeneity in

#### **BOX 106-6 Disorders of Gluconeogenesis**

- Fructose-1,6-diphosphatase deficiency
- Phosphoenolpyruvate-carboxykinase deficiency
- Pyruvate carboxylase deficiency

expression of this disorder, deficient leukocyte activity is diagnostic; however, normal leukocyte activity does not rule out fructose-1,6-diphosphate deficiency because a form of the disorder occurs with normal leukocyte activity and isolated liver enzyme deficiency. In this case a liver biopsy will be indicated.

Treatment of acute, severe episodes involves controlling hypoglycemia and acidosis through continuous intravenous glucose infusion and administration of sodium bicarbonate. Once the hypoglycemia and acidosis are corrected, maintenance therapy is directed at preventing prolonged periods of fasting. This task can be accomplished through continuous nasogastric feedings or intake of uncooked cornstarch after 1 year of age. Dietary restriction includes elimination of fructose, sucrose, glycerol, and sorbitol, which may precipitate an acute life-threatening event. Follow-up should include monitoring growth and development. With advancing age, issues with fasting will improve, which is thought to occur because of an increased capacity for the liver to store glycogen, lowering the need for gluconeogenesis.

#### **Phosphoenolpyruvate-Carboxykinase Deficiency**

Phosphoenolpyruvate-carboxykinase is an important target in the regulation of gluconeogenesis. PEPCK deficiency is a rare disorder that results from a defect localized to chromosome 20q13.31. PEPCK is active in mitochondria and the cytosol. The time of clinical presentation ranges from the neonatal period to early infancy. Affected infants exhibit hypoglycemia. Other clinical features include nonspecific symptoms such as lethargy, hypotonia, and failure to thrive. Systemic manifestations include hepatomegaly with hepatocellular damage, fatty liver, renal tubular acidosis, and fatty kidneys. PEPCK is involved in the conversion of oxaloacetate into phosphoenolpyruvate. Deficiency in PEPCK blocks the conversion of pyruvate, lactate, alanine, and the citric acid-cycle intermediates to glucose. Measuring PEPCK activity from freshly obtained liver biopsy samples is necessary to make the diagnosis. Because 2 isoforms of PEPCK can occur, one found in the mitochondria and the other in the cytosol, liver biopsy samples require fractionating to make the diagnosis. Initial treatment involves correction of hypoglycemia with intravenous glucose and sodium bicarbonate. Once stable, avoidance of fasting and use of nasogastric feeds or uncooked cornstarch after 1 year of age at bedtime are the mainstay of therapy. Unfortunately, the long-term prognosis is poor, with patients succumbing to hypoglycemia and neurologic injury.

#### **Pyruvate Carboxylase Deficiency**

Pyruvate carboxylase (PC) deficiency is an autosomal-recessive disorder. The PC gene is located on chromosome 11 and has 3 distinct clinical presentations: a severe neonatal form, a milder form occurring later with psychomotor retardation, and a benign form occurring with recurrent episodes of lactic acidosis and mild neurologic deficits. In the neonatal form, infants exhibit seizures, hypotonia, spasticity, renal tubular acidosis, and hepatic dysfunction. PC is responsible for the conversion of pyruvate and carbon dioxide to

oxaloacetate. PC is essential in supplying oxaloacetate to the citric acid cycle and thus in providing the necessary substrate for other metabolic pathways such as gluconeogenesis, lipogenesis, and glycerogenesis. Laboratory analysis reveals lactic acidosis, hypoglycemia, and increased ammonia, lysine, citrulline, and alanine levels. Hyperammonemia distinguishes PC deficiency from the other disorders of gluconeogenesis and should therefore be considered in any newborn infant with severe neurologic abnormalities. Diagnosis is made by measuring PC enzymatic activity in liver or skin tissue. Treatment revolves around addressing the lactic acidosis and hypoglycemia (see previous discussion). The hyperammonemia can be treated by providing an alternate source of 4-carbon intermediates (aspartate or citrate) as it replenishes oxaloacetate. The prognosis for infants presenting in the neonatal period is especially poor, with survival beyond 3 months of life rare.

### **Process 4: Fatty Acid Oxidation and Ketogenesis**

#### **Pathophysiologic Features**

Fatty acid oxidation (FAO) disorders include medium-chain acyl-coenzyme A (CoA) dehydrogenase deficiency (MCADD), which is the most common of these metabolic disorders. Through the  $\beta$ -oxidation pathway, fatty acids provide energy-yielding substrates during periods of fasting and stress. This process is typically initiated after fasting for more than 12 hours. Normal metabolism of endogenous fats begins with lipolysis; this process, in turn, releases free fatty acids, resulting in an increase in plasma concentration. Free fatty acids are then bound to albumin and transported to other tissues. Short- and medium-chain fatty acids cross the mitochondrial membrane without esterification, unlike long-chain fatty acids. After conversion of long-chain fatty acids to their CoA esters, they react with L-carnitine to form acylcarnitine esters. The fatty acylcarnitine complex is then transported across the mitochondrial membrane. Once transported inside the mitochondria, the fatty acid-acyl-CoA complex will undergo  $\beta$ -oxidation, which is an important source of energy for the body during times of prolonged fasting and metabolic stress.  $\beta$ -Oxidation involves successive shortening by 2 carbon atoms ultimately releasing the end product acetyl-CoA.

In the muscle, acetyl-CoA enters the citric cycle (ATP production). While in the liver, acetyl-CoA is used to synthesize the ketone bodies 3-hydroxybutyrate and acetoacetate. These ketones can then be used as a secondary fuel source for most tissues, particularly the brain. Inborn errors involving intramitochondrial FAO diminish the supply of nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide (FAD) available for mitochondrial oxidative phosphorylation, decreasing the formation of ATP. Therefore, disorders related to FAO may lead to multiorgan failure secondary to acute ATP deficiency. Clinical features of FAO disorders include hypotonia, cardiomyopathy, coma, and hepatomegaly (fatty liver). The clinical presentation may be confusing and misleading; for example, hyperammonemia may suggest Reye syndrome, and

unexpected death may be taken as sudden infant death syndrome. Many patients have a family history of sudden death in siblings during infancy. The classic presentation is hypoketotic hypoglycemia, indicating impairment in FAO. Patients can exhibit vomiting and lethargy, which occurs after fasting. Intercurrent illness can induce prolonged fasting, potentially unmasking a primary underlying disorder of FAO. Diagnosis can be delayed considerably, given that some patients reach adulthood before experiencing a prolonged fasting episode that induces symptoms. Some affected individuals remain asymptomatic for life. This great variability in the clinical presentation can prevent prompt diagnosis in some patients. Pregnancies complicated by either acute liver failure of pregnancy or HELLP syndrome have been associated with fetuses affected with disorders of FAO. The physician must be aware of these prenatal clues and consider all newborns delivered in mothers with acute liver failure of pregnancy or HELLP syndrome to be at risk for disorders of FAO. Box 106-7 lists the disorders of fatty acid oxidation.

Table 106-7 lists the distinguishing metabolic markers encountered with the fatty acid-oxidation disorders. These markers can be obtained by analysis of

acylcarnitine profiles in plasma, blood spots (Guthrie cards), and urine.

### Medium-Chain Acyl-CoA Dehydrogenase Deficiency

MCADD is the most common disorder in the FAO pathway. The estimated frequency is 1 in 5,000 to 10,000 live-born infants. MCADD testing is currently included on newborn metabolic screening panels in many states. It is an autosomal-recessive disorder, with the A985G mutations occurring with the highest frequency. The worldwide prevalence is shown in Table 106-8. MCADD produces hypoketotic hypoglycemia after a fasting period of 8 to 12 hours in neonates or potentially earlier if an acute intercurrent illness is present. The most common time for presentation of MCADD is after 3 months of age, when infants typically stop night feedings. Older children may need to be fasting for 18 to 24 hours before symptoms become evident.

The first step in treatment is focused on avoiding prolonged fasts. As noted previously, this is not usually an issue for newborns because they generally feed every 2 to 3 hours. As individuals with this condition get older, they generally tolerate longer fasting intervals. In neonates and infants, going longer than 6 hours without a feeding should be avoided. At 1 year of age, raw cornstarch may be instituted to supply a slow release source of glucose for up to 8 hours. This approach cannot be used in children younger than 1 year because of enzyme immaturity and inability to handle the osmotic load.

Plasma L-carnitine levels should be checked as soon as the diagnosis is suspected. Some individuals may have low plasma L-carnitine levels that require supplementation with oral carnitine. Low L-carnitine levels cause a progressive cardiomyopathy. Another function of L-carnitine is to remove short-chain and

medium-chain fatty acids from the mitochondria so as to maintain CoA levels. These fatty acids accumulate as a result of normal and abnormal FAO. This mechanism prevents the build-up in the mitochondria of short-chain and medium-chain fatty acids that may interfere with the energy production essential to the normal function of the cell. In individuals who have normal plasma L-carnitine levels, experts have recommended that L-carnitine not be given because it may result in increased stress on the FAO pathway by its function in assisting the transport of long-chain fatty acids into the mitochondria for oxidation. Box 106-8 lists other FAO defects and characteristic findings.

### Process 5: Disorders of Hormonal Regulation—Deficiency of Counterregulatory Hormones

When a newborn experiences hypoglycemia, a cascade of hormonal responses is activated to counter and restore blood glucose levels to normal. The first physiological response suppresses insulin secretion. This event is followed by an increase in counterregulatory hormones if hypoglycemia persists. The counterregulatory hormones are listed in Table 106-9.

These counterregulatory hormones stimulate glycogenolysis, gluconeogenesis, adipose tissue lipolysis, and hepatic ketogenesis. Some overlap in counterregulatory hormone effects occurs; thus if 1 system fails, partial compensation occurs by another hormone. Deficiencies in GH, glucagon, cortisol, and insulin-like growth factors may contribute

to hypoglycemia. Box 106-9 describes disorders of hormonal regulation.

### Pituitary Deficiency

Congenital pituitary deficiency is the second most common cause of persistent neonatal hypoglycemia, after congenital hyperinsulinism. Physical examination may range from a normal examination to identifying abnormalities involving midline defects such as single central incisor, optic nerve hypoplasia, and cleft lip or palate. Another physical finding is the presence of a microphallus and undescended testis in male newborns secondary to gonadotropin deficiency. Therefore the association of hypoglycemia and microphallus should alert the physician to the possibility of panhypopituitarism. Female newborns with gonadotropin deficiency have normal external genitalia because the development of the female external genitalia does not require the presence of gonadotropin-releasing hormone, luteinizing hormone, follicle-stimulating hormone, or ovarian hormones. The unopposed insulin secretion found with congenital pituitary deficiency can result in clinical findings similar to hyperinsulinism.

### Adrenal Deficiency

Adrenal insufficiency is rare cause of hypoglycemia in the newborn infant and occurs in cases of congenital adrenal hypoplasia or aplasia and adrenal hemorrhage. The resulting cortisol deficiency can be life threatening, making early recognition imperative.

### Non-Hypoglycemic Neonatal Onset Metabolic Disease

A variety of metabolic conditions exist that do not have hypoglycemia as a presenting symptom but will produce acidosis or hyperammonemia. Many of these conditions occur initially with feeding intolerance or irritability (or both) that can progress to increasing lethargy, seizures, and coma. If untreated, then the classic forms of these conditions cause severe neurologic devastation or death. Many of these metabolic conditions are now included on newborn screening programs in several states. However, screening results can take up to 7 days to return, and, in many of these conditions, onset of symptoms may begin at 3 days of life. Keeping these conditions in mind will allow the physician to intervene and minimize the effect on an affected neonate.

An important term to clarify in regard to treatment for some of these conditions is *natural protein*, which is a protein obtained from complete sources—that is, standard baby formulas or table foods.

**L-CARNITINE DEFICIENCY.** Carnitine deficiency is an autosomal-recessive disease localized to chromosome 5q31. Some individuals have low plasma L-carnitine levels that require supplementation with oral L-carnitine as a result of decreased enzyme activity necessary for carnitine uptake in the intestine and kidney. The reduction in L-carnitine will ultimately affect  $\beta$ -oxidation by limiting the entry of acyl-CoA esters into the mitochondria. Thus L-carnitine removes short-chain and medium-chain fatty acids from mitochondria to maintain CoA levels. These fatty acids

**BOX 106-8 Rare Fatty Acid Oxidation Defects**

The prevalences of these defects are unknown, although LCADD is likely the most common. The inheritance of these conditions is autosomal recessive: Short-chain acyl-coenzyme A (CoA) dehydrogenase deficiency (SCADD), long-chain acyl-CoA dehydrogenase deficiency (LCADD), trifunctional enzyme deficiency, long-chain hydroxyacyl-acyl-CoA dehydrogenase deficiency (LCHADD), very long-chain acyl CoA dehydrogenase deficiency (VLCADD)

**CLINICAL FINDINGS**

- Seizures
- Hypotonia
- Cardiomyopathy
- Sudden infant death syndrome

**LABORATORY FINDINGS**

- Hypoketotic hypoglycemia
- Abnormal liver function tests

**SPECIALTY BIOCHEMICAL TESTING**

- Organic acids have a typical profile
- Acylcarnitine profile
- Plasma amino acids are normal
- Enzyme testing is available but difficult

**ACUTE TREATMENT**

- Intravenous glucose
- Formula containing medium-chain triglycerides (medium-chain triglyceride oil)—Pregestimil
- Supportive care for cardiomyopathy

- Adrenal deficiency (cortisol deficiency)

accumulate as a result of normal and abnormal FAO. This mechanism prevents the buildup in the mitochondria of short-chain and medium-chain fatty acids that may interfere with energy production essential to the normal function of the cell. In certain organic acidemias, L-carnitine will also bind the offending organic acid for removal, that is, propionic acid. As noted previously, in well individuals who have FAO disorders and normal plasma L-carnitine levels, experts have recommended that L-carnitine not be given because it may result in increased stress on the FAO pathway by its function in assisting the transport of long-chain fatty acids into the mitochondria for oxidation. Clinically low L-carnitine levels cause

a progressive cardiomyopathy, encephalopathy, and hypoketotic hypoglycemia.

Low levels of L-carnitine in serum and tissue are diagnostic.

Treatment with L-carnitine 100 to 200 mg/kg/day can result in a dramatic response. In severe cases peritoneal dialysis has been found to be a safe, effective, and easy way to remove excess offending metabolites in neonates and infants. Some debate has occurred over hemodialysis in neonates because of reports of poor outcomes; however, it has also been used successfully and with more efficient metabolite removal. Much can depend on the experience of persons who implement the hemodialysis in the neonatal setting.

Ammonul (sodium phenylacetate–sodium benzoate) is an intravenous plasma ammonia-binding solution that will lower ammonia levels.

**GALACTOSEMIA.** Galactosemia has a prevalence of 1 in 40,000 to 60,000 live births. Individuals with the classical form of galactosemia have a complete inability to metabolize galactose. Galactosemia is an autosomal-recessive condition. The primary defect in the classical form of galactosemia is deficiency of galactose-1-phosphate uridylyltransferase. Deficiency in this enzyme results in an accumulation of galactose-1-phosphate and galactose. In the newborn period, galactosemia

can be lethal within 2 weeks. Many states test for galactosemia as part of the newborn metabolic screening program. However, clinical signs generally emerge before the newborn screening results are available. Clinical features include jaundice, increased reducing substances in the urine, abnormalities in prothrombin time and partial thromboplastin time, and liver dysfunction. The primary cause of death at 1 to 2 weeks of age is *E coli* infection resulting from an affected infant's increased susceptibility to infection.

An important fact when considering a diagnosis of galactosemia is that urine-reducing substances will be markedly positive (4 or more urine-reducing substances) in the context of a normal screening using a glucose meter, which is specific for glucose. This circumstance should alert the physician to the fact that the infant is excreting a sugar other than glucose into the urine. Care must be taken in performing invasive procedures such as a lumbar puncture in a neonate because the associated hepatic dysfunction may cause a severe coagulopathy and bleeding. Despite the importance of evaluating the infant for possible meningitis, affected infants are at significant risk of intraspinal bleeding that may cause paralysis.

The risk of lethal *E coli* infection is high several days after birth because of increasing accumulation of abnormal metabolites. Once the galactose metabolites are lowered the risk of *E coli* infection is similar to that of the general neonatal population. In the past, authorities thought that tight control of galactose intake would prevent long-term sequelae. However, it is now apparent that older patients with galactosemia are at high risk for specific medical issues despite minimizing galactose intake. Long-term medical complications include speech delays, premature ovarian failure in women, and, in some individuals, onset of tremor and ataxia. These complications have been associated with the *Q188R* mutation, which results in complete absence of the galactose-1-phosphate uridylyltransferase enzyme.

The primary goal in management of neonates suspected of having or diagnosed with galactosemia is to minimize galactose intake. Because breast milk and standard cow milk-based infant formulas contain lactose, these feedings must be stopped. Lactose is a disaccharide that consists of glucose and galactose. Metabolism of lactose releases the galactose, resulting in elevations in galactose metabolites. Soy milk-based infant formulas do not have galactose and provide a safe alternative infant feeding. If a neonate has clinical manifestations of galactosemia, then a sepsis evaluation should be performed even after they are placed on a soy milk formula. Blood and urine cultures should be obtained, but a spinal tap should be avoided, given the risks noted previously, until results of coagulation studies confirm normal coagulation.

Long-term dietary management requires intensive nutritional counseling to avoid galactose-containing foods. The goal of the diet is to incorporate soy-based products and to avoid galactose-containing products. Individuals with galactosemia must remain on this diet for life.

**FRUCTOSEMIA.** Fructosemia does not occur in the neonatal period but surfaces when sucrose, fructose, or fruits are introduced in the infant's diet.

**Figure 106-9** The biotin cycle has not yet been localized to a specific cellular compartment; therefore this cycle is not displayed on the master biochemical pathway figure.

**BIOTINIDASE DEFICIENCY.** Biotinidase deficiency is an autosomal-recessive condition with a prevalence of approximately 1 in 60,000. The gene for biotinidase is located on chromosome 3q25. Biotinidase is an enzyme involved in the generation and maintenance of biotin, an essential water-soluble vitamin. Figure 106-9 reveals how biotinidase is generated. Biotin is an essential cofactor that covalently binds to the  $\epsilon$ -amino group of a specific lysine residue to 5 carboxylases: pyruvate carboxylase, 3-methylcrotonyl-CoA carboxylase, propionyl-CoA carboxylase, and the 2 identified isoforms of acetyl-CoA carboxylases have been identified—acetyl-CoA carboxylase  $\alpha$  and acetyl-CoA carboxylase  $\beta$ . The functional activity is shown by the red-circled enzymes in Figure 106-8. Each biotin-dependent carboxylase has distinct roles involving amino acid synthesis, fatty acid biosynthesis/oxidation, and gluconeogenesis. Propionyl-CoA carboxylase and 3-methylcrotonyl-CoA carboxylase are important for protein metabolism; pyruvate carboxylase is localized in the mitochondria and is key for gluconeogenesis and acetyl CoA carboxylase  $\alpha$  is required for fatty acid synthesis while acetyl-CoA carboxylase  $\beta$  is required for fatty acid oxidation in the mitochondria. Figure 106-10 illustrates the role of biotinidase, the sodium-dependent multivitamin transporter and holocarboxylase synthetase in the homeostasis of biotin. Infants with biotinidase deficiency may become symptomatic within several days to several months after birth. The deficiency can occur acutely with seizures, vomiting, diarrhea, feeding difficulties, tachypnea from acidosis, and apnea. Laboratory findings may include hyperammonemia, ketolactic acidosis, and organic aciduria. If biotinidase deficiency is not detected early and treatment initiated, then late manifestations of biotinidase deficiency may cause hypotonia, ataxia, hearing loss, optic atrophy, alopecia, abnormalities in cellular immunity, basal ganglia

**Figure 106-10** Biotin and its homeostasis. (From Zemleni J, Hassan YI, Wijeratne SS. Biotin and biotinidase deficiency. *Expert Rev Endocrinol Metab.* 2008;3:715–724. Reprinted with permission of FUTURE DRUGS LTD.)

calcifications, intellectual disability, skin rash, and seborrheic dermatitis. Newborn screening for biotinidase deficiency is performed in most states.

Treatment involves large doses of biotin: 20 mg/day is usually sufficient for life. Biotin supplementation prevents all of the disease manifestations. In some cases, with neonatal onset, seizures may begin during the first few days of life, necessitating antiepileptogenic medication in addition to supplemental biotin. Usually, as the biotin takes effect, the seizure medication can be discontinued.

**ORGANIC ACIDEMIAS.** The organic acidemias are a set of conditions that tend to occur in a similar way and have similar treatments. Organic acids form from the breakdown of branched-chain amino acids, methionine, and threonine in most cases. In individuals with enzyme deficiencies, accumulation of intermediate metabolites can cause severe illness and death. Affected infants tend to exhibit severe acidosis within several days of life. The physician should identify the involved organic acids because treatment includes use of specialized, amino acid–modified (free) infant formulas once the infant is stabilized after acute therapies.

*Methylmalonic acidemia* has a prevalence of 1 in 40,000 to 50,000 live births. It is an autosomal-recessive condition that results from methylmalonyl-CoA mutase deficiency, or it may also result from a defect in cobalamin (vitamin B12) metabolism.

*Propionic acidemia* has a prevalence of 1 in 50,000 to 100,000 live births. It is an autosomal-recessive condition resulting from the deficiency of propionyl-CoA carboxylase, a biotin-dependent enzyme.

*Isovaleric acidemia* has an unknown prevalence. It is an autosomal-recessive condition that results from isovaleryl-CoA dehydrogenase deficiency. This enzyme is

involved in leucine metabolism; however, leucine is not elevated in these individuals because of an irreversible step before isovaleryl-CoA dehydrogenase.

Infants with methylmalonic acidemia and propionic acidemia usually exhibit poor feeding, irritability, respiratory difficulty with tachypnea and labored breathing, severe and repetitive vomiting, cerebral edema, and progression to coma and death over a period of days to weeks. Infants affected by isovaleric acidemia can exhibit the previously listed findings along with a strong *sweaty sock* odor. This sign may not be noticed if the neonate has been catheterized or if the urine is dilute.

**Evaluation.** Laboratory findings of infants with organic acidemias include metabolic acidosis on a blood gas sampling, leukopenia, thrombocytopenia, and ketosis. Hyperammonemia can be present in methylmalonic acidemia and propionic acidemia. Hyperammonemia is thought to be the result of secondary inhibition of the urea cycle by the abnormal metabolites generated. As a consequence, affected individuals may have normal blood urea nitrogen levels despite evidence of dehydration caused by a decreased ability to generate urea.

Diagnosis of an organic acidemia requires analysis of urine organic acid patterns. Characteristic excretion patterns are identifiable for various organic acidemias. Plasma amino acid analysis is significant for a marked elevation of glycine and is the reason for the categorization of methylmalonic acidemia and propionic acidemia as ketotic hyperglycinemias. In isovaleric acidemia, glycine is not elevated, which may be the result of the conjugation of isovaleryl metabolites to form isovalerylglycine. Elevations of valine, methionine, isoleucine, and threonine can be seen in methylmalonic acidemia and propionic acidemia.

**Treatment.** Treatment for methylmalonic acidemia and propionic acidemia involves therapy to lower the level of the elevated plasma organic acid. Beneficial therapies in the acute management of these conditions include dialysis to lower potentially elevated ammonia and the offending plasma organic acid, and L-carnitine in a dosage of 200 to 300 mg/kg/day to bind plasma organic acids and replenish L-carnitine. Natural protein intake should also be limited to 1.0 to 1.2 g/kg/day in the acute decompensation. Additionally, though not routinely available, treatments such as *metabolic* parenteral solutions that do not contain valine, methionine, isoleucine, and threonine and administration of intravenous sodium phenylacetate–sodium benzoate (Ammonul) to correct hyperammonemia may be helpful.

Treatment of isovaleric acidemia is as described for methylmalonic acidemia and propionic acidemia, with the following exceptions: Oral glycine is given at a dose of 500 mg/kg/day to bind isovaleryl metabolites, and parenteral solutions should not contain leucine.

Long-term treatment involves use of specialty commercial formulas to prevent buildup of the offending organic acid. Natural protein is typically maintained at 1.0 to 1.5 g/kg/day, with the remainder of protein and calories provided by the specialty formula.

**UREA-CYCLE DEFECTS.** Urea-cycle defects are a category of conditions that involve primary dysfunction of the urea cycle. Several enzyme deficiencies cause these conditions, and most are autosomal recessive. A notable exception is ornithine transcarbamylase (OTC) deficiency, an inherited X-linked trait that is the most common urea-cycle disorder. This inheritance pattern results in a more severe presentation in male patients, with female patients typically minimally affected, if at all. The prevalence of OTC deficiency is approximately 1 in 80,000 live births. Box 106-10 lists the diagnostic criteria for OTC deficiency.

The clinical presentation of urea-cycle disorders is similar to the presentation of other metabolic conditions. However, acidosis is usually not a presenting component of these conditions. Lactic acidosis may become prominent once the patient becomes critically ill. Presenting signs often include anorexia, irritability, lethargy, vomiting, somnolence, asterixis (rare), obtundation, coma, cerebral edema, and combativeness and disorientation (in older individuals). Death may occur if treatment is not rapid or effective. Laboratory findings of importance are hyperammonemia (usually >150 mcmol/L; can be as high

as 2,000–4,500 mcmol/L), low blood urea nitrogen, and respiratory alkalosis. Metabolic acidosis is *not* present unless the patient is in critical condition. Characteristic amino acid profiles confirm the specific urea-cycle defect.

Acute treatment of urea-cycle disorders involves dialysis to remove the ammonia, provision of calories by administration of 20% lipid solutions, infusions of intravenous sodium phenylacetate–sodium benzoate (Ammonul), and specially formulated formula once oral intake is possible. An infant with OTC deficiency requires infusions of arginine in doses of 200 mg/kg/day and intravenous glucose.

In certain cases, when no response or sluggish response to pharmacologic therapy occurs, the health care professional must consider hemodialysis.

Long-term urea-cycle defects are treated by providing formulas that contain essential amino acids along with natural protein at approximately 1.0 to 1.5 g/kg/day. Typically, affected infants require treatment with oral ammonia-binding agents such as sodium benzoate or Buphenyl to maintain plasma ammonia at an acceptable level. This treatment allows for maintenance of ammonia levels close to the normal range, in most cases, while the individual is well. However, affected patients remain susceptible to transient elevations of ammonia during illness even while on ammonia-binding agents. During episodes of illness, all protein should be stopped for 24 hours and a formula consisting of carbohydrates and fats administered. Protein is gradually reintroduced into the diet once the ammonia level declines. An important point to note is that protein must be given after 24 hours to prevent endogenous protein catabolism and further worsening of the hyperammonemia. If levels are dramatically elevated, then the acute management protocol described previously should be initiated. Depending on the severity of the condition, liver transplant should be considered, especially if the individual does not respond to medical management or requires frequent hospitalizations.

**TYROSINEMIA TYPE 1.** Tyrosinemia type 1 is inherited in an autosomal-recessive manner. Tyrosinemia type 1 results from a deficiency of fumarylacetoacetate hydrolase encoded by the FAH gene, which is the only gene responsible for the disease. Tyrosinemia type 1 has a prevalence of 1 in 1,800 in certain regions of Quebec and is estimated to be approximately 1 in 100,000 elsewhere. Tyrosine is usually metabolized to acetoacetate; however, in classical tyrosinemia type 1, fumarylacetoacetate hydrolase deficiency will result in excess succinylacetone. Succinylacetone is toxic and leads to the clinical findings in tyrosinemia type 1. Type 1 tyrosinemia is an acute-onset disorder that initially produces diffuse liver dysfunction, which without intervention progresses to liver failure and death. Other clinical manifestations include renal tubular dysfunction resulting in growth failure and rickets. This enzyme deficiency results in accumulation of metabolites that require metabolism via alternative pathways.

Acute management of tyrosinemia type 1 has been revolutionized recently with the development of nitisinone (Orfadin) (2-[2-nitro-4-trifluoro-methylbenzoyl]-1,3

#### **BOX 106-10 Ornithine Transcarbamylase Deficiency Diagnosis**

- DNA analysis

cyclohexanedione). This medication inhibits enzyme function proximal to fumarylacetoacetate hydrolase, preventing the accumulation of fumarylacetoacetate and its conversion to succinylacetone which results in biochemically transforming tyrosinemia type 1 into tyrosinemia type 2. (The enzyme defect in tyrosinemia type 2 is a deficiency of hepatic cytosol tyrosine aminotransferase activity.) Treatment should be started immediately once the diagnosis of tyrosinemia type 1 is confirmed. Tyrosinemia type 2 is a milder form of tyrosinemia that results in cataract formation and skin findings without the hepatic involvement. However, even with administration of nitisinone, plasma tyrosine levels will require continued monitoring and control through dietary intervention to prevent the ocular and skin findings that are associated with tyrosinemia type 2.

Liver transplantation is reserved for patients presenting with severe liver failure that does not respond to nitisinone.

Several commercial formulas are available that do not contain tyrosine. These formulas can be used to control plasma tyrosine levels. Typically, natural protein is kept at 1.0 to 1.5 g/kg/day, with the remainder of protein and calorie requirements provided by the tyrosine-deficient formulas.

**PHENYLKETONURIA.** Phenylketonuria (PKU) does not exhibit acutely in the neonatal period; however, given that PKU is among the most common inborn errors of metabolism, with a prevalence of 1 in 10,000 to 15,000 live births, a brief mention is provided here. The primary defect is in phenylalanine hydroxylase activity, and it results in elevations in phenylalanine. Chronic phenylalanine elevations cause brain injury that may progress to severe intellectual disability if the condition is not treated.

Newborn screening for PKU does not differentiate between the classical form of PKU and rare forms that result from bipterin deficiency. The active form of bipterin, tetrahydrobiopterin, is a cofactor for phenylalanine hydroxylase. Up to 2% of affected individuals with hyperphenylalaninemia have a bipterin abnormality that disrupts neurotransmitter metabolism in addition to phenylalanine metabolism.

PKU was one of the first conditions that was screened for in newborns and was the model condition for dietary management of an inborn error of metabolism. Numerous commercial formulas and low-protein products are available to aid in maintaining plasma phenylalanine concentrations at an appropriate level.

Individuals with bipterin abnormalities do not typically respond to dietary manipulations alone, given that the cofactor deficiency also adversely affects neurotransmitter production. Bipterin deficiency is treated by replacing the precursors to the affected neurotransmitters, folinic acid in some cases, and providing the active form of the cofactor, tetrahydrobiopterin. For some affected patients, treatment with tetrahydrobiopterin may make additional therapy unnecessary. A growing body of evidence indicates that up to 10% of individuals with phenylalanine hydroxylase deficiency may be responsive to tetrahydrobiopterin.

**MAPLE SYRUP URINE DISEASE.** Maple syrup urine disease (MSUD) has an approximate prevalence of 1 in 120,000 to 500,000 live births. The highest incidence occurs in the Mennonite population in Pennsylvania, affecting approximately 1 in 176 newborns. MSUD is an autosomal-recessive condition; its primary defect is in the metabolism of the branched-chain amino acids, including isoleucine, leucine, and valine. The enzyme involved is branched-chain alpha-keto dehydrogenase complex. Acute clinical signs begin several days after birth when branched-chain amino acids accumulate as infants increase their feeding intake. Presenting signs include poor feeding, irritability, and stereotypical seizures characterized by bicycling motions of the arms and legs. In addition, the infant and the infant's urine have an odor of maple syrup. Lethargic infants rapidly progress to coma and death.

Therapy involves extracting the branched-chain amino acids from plasma, thereby reducing total body concentration of these amino acids. Dialysis is necessary to reduce the elevated amino acid levels rapidly in an affected neonate. Peritoneal dialysis has been shown to be safe and effective in lowering these amino acids; however, in severe cases, hemodialysis may be necessary. Once the leucine level is reduced to approximately 10 mg/dL, dialysis can be discontinued. Thereafter, the treatment goal is to maximize caloric intake to prevent catabolic breakdown of endogenous proteins, resulting in continued elevations of the branched-chain amino acids. Initially, 20% lipid solutions in a dose of 2 g/kg/day are administered in conjunction with 12.5% to 20% dextrose to prevent catabolism. Parenteral nutrition solutions without branched-chain amino acids are used to control branched-chain amino acid levels while enteral nutrition is implemented.

A thiamine (vitamin B1)-responsive form of MSUD has been identified. Thiamine supplementation corrects the enzyme deficiency, resulting in the ability to tolerate normal protein in normal amounts. Usually, 10 mg/day of thiamine will correct the hyperbranched-chain aminoaciduria without the need for dietary intervention.

In cases in which thiamine does not have any effect, several commercial formulas are available that do not contain the branched-chain amino acids, which can be used as a protein source. Additional calories can be provided by other specialty formulas that contain only fats and carbohydrates. As the branched-chain amino acids decline into the physiologic range, small amounts of natural protein are required in the form of a standard formula to prevent branched-chain amino acid deficiencies. Natural protein can be started at 1.0 to 1.25 g/kg/day and then adjusted to keep the branched-chain amino acid levels within normal range. The remainder of protein requirements, 2.5 to 3.0 g/kg/day, can be achieved with the specialty formula that lacks the branched-chain amino acids.

Long-term management of MSUD involves a low-protein diet, continued use of specialty formulas, and intensive monitoring of plasma isoleucine, valine, and leucine levels.

**HOMOCYSTINURIA.** Homocystinuria has a prevalence of approximately 1 in 200,000. It is an autosomal-recessive condition. Most newborn screening programs

test for plasma methionine concentrations to evaluate for the presence of the condition, given that methionine is elevated in individuals with homocystinuria. However, methionine can be elevated in a variety of conditions that cause liver disease, or it may occasionally be transiently elevated in the newborn. Cystathionine  $\beta$ -synthase is a critical enzyme in the metabolism of homocysteine. Deficiency of cystathionine  $\beta$ -synthase is the most common cause of homocystinuria. Cobalamin plays a critical role in the formation of cofactors for the metabolism of methylmalonic acid and homocysteine.

The acute findings in homocystinuria include thromboembolism and seizures. Homocysteine is an endothelial irritant that causes lesions resulting in intravascular clot formation. High concentrations of plasma homocysteine can lower seizure thresholds and may be noted as a presenting symptom. Untreated or inadequately treated patients develop intellectual disability and developmental delay, psychiatric disorders, ectopia lentis, scoliosis, and osteoporosis. Fifty percent of affected individuals die before the age of 25 years.

Approximately 50% of individuals are responsive to vitamin B6, a cofactor for cystathionine  $\beta$ -synthase. Individuals who respond to vitamin B6 do well and do not require further treatment. Nonresponders to vitamin B6 therapy must be maintained on a restricted methionine and cystine diet for life. Natural protein intake at 1.0 to 1.5 g/kg/day via a low-protein diet and formula are necessary. Betaine, a trimethylglycine, is formed through the oxidation of choline and has shown promising results in the management of individuals with homocystinuria. It converts homocysteine to methionine and permits reduction of the dietary restrictions. Experts recommend that methionine

levels be kept below 1,000  $\mu\text{mol/L}$  to prevent cerebral edema. Studies have not yet been conducted on neonates or infants to evaluate for safety of this therapy.

**COBALAMIN DISEASE.** Seven subtypes of cobalamin (Cbl) disorders, designated Cbl A through G, have been identified. This group of cobalamin disorders can cause elevations in methylmalonic acid only (Cbl A and B), a combination of methylmalonic acid and homocysteine elevations (Cbl C, D, and F), or homocysteine elevations only (Cbl E and G). These disorders result from abnormal Cbl (vitamin B<sub>12</sub>) metabolism or transport.

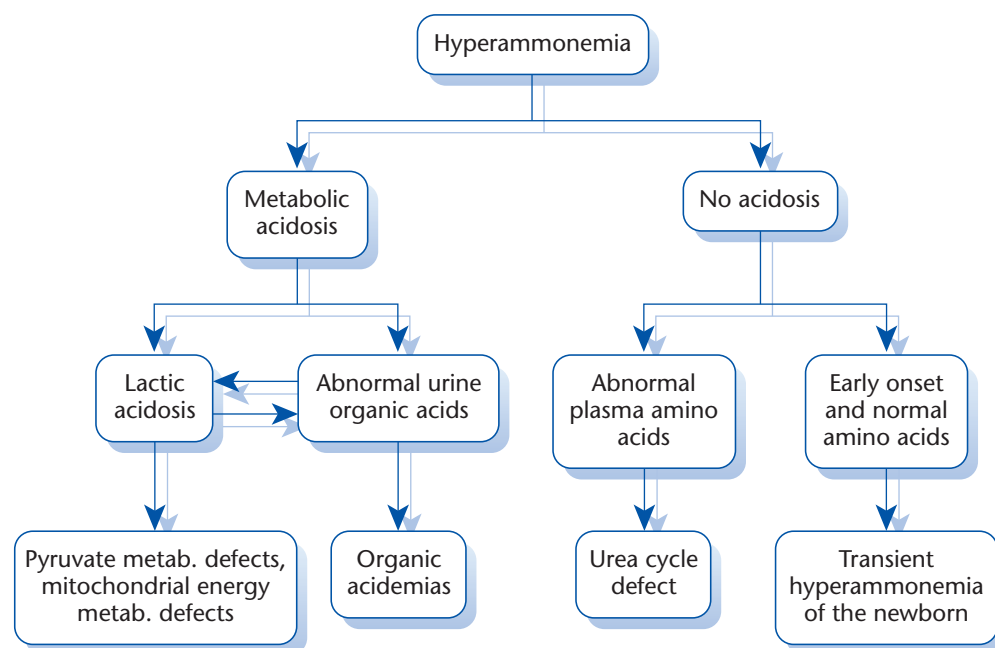

Administration of hydroxycobalamin, the active form of Cbl, corrects the biochemical abnormalities and usually allows for a complete recovery. Hydroxycobalamin is administered subcutaneously.

#### **PYRUVATE-DEHYDROGENASE COMPLEX DEFICIENCY.**

The pyruvate-dehydrogenase complex plays a critical role in metabolizing the product of glycolysis, pyruvate, to acetyl-CoA. Pyruvate-dehydrogenase complex deficiency is a mitochondrial disorder that can exhibit acutely in the neonatal period with a severe lactic acidosis. X-linked and autosomal-recessive forms have been identified. This condition is not currently screened for on state newborn metabolic testing; however, prompt intervention can minimize the effects of accumulating toxic metabolites.

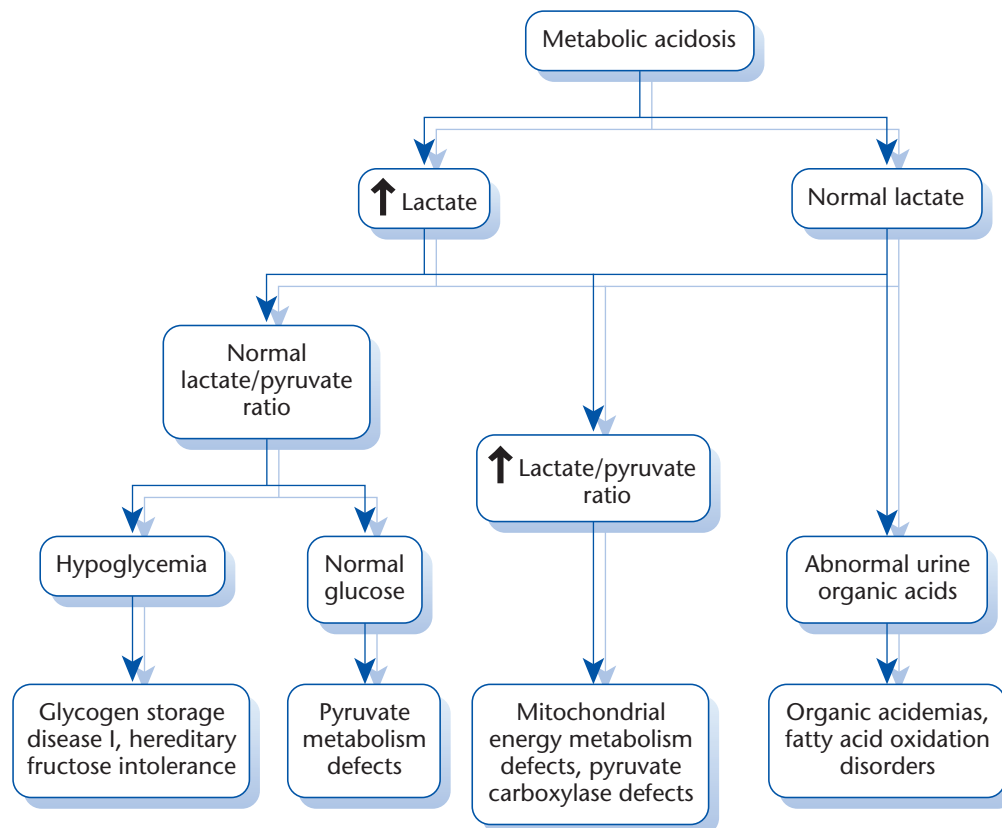

Minimizing carbohydrate and glucose intake lowers the levels of lactic acid. Formulas that are high in protein and fat are commercially available. Five-percent dextrose is tolerated well; however, higher glucose concentrations can cause increased lactate levels. As long as the lactate is controlled, these infants have a good chance of surviving the neonatal period.

The algorithms shown in Figure 106-11, Figure 106-12, and Figure 106-13 can assist the physician with inborn

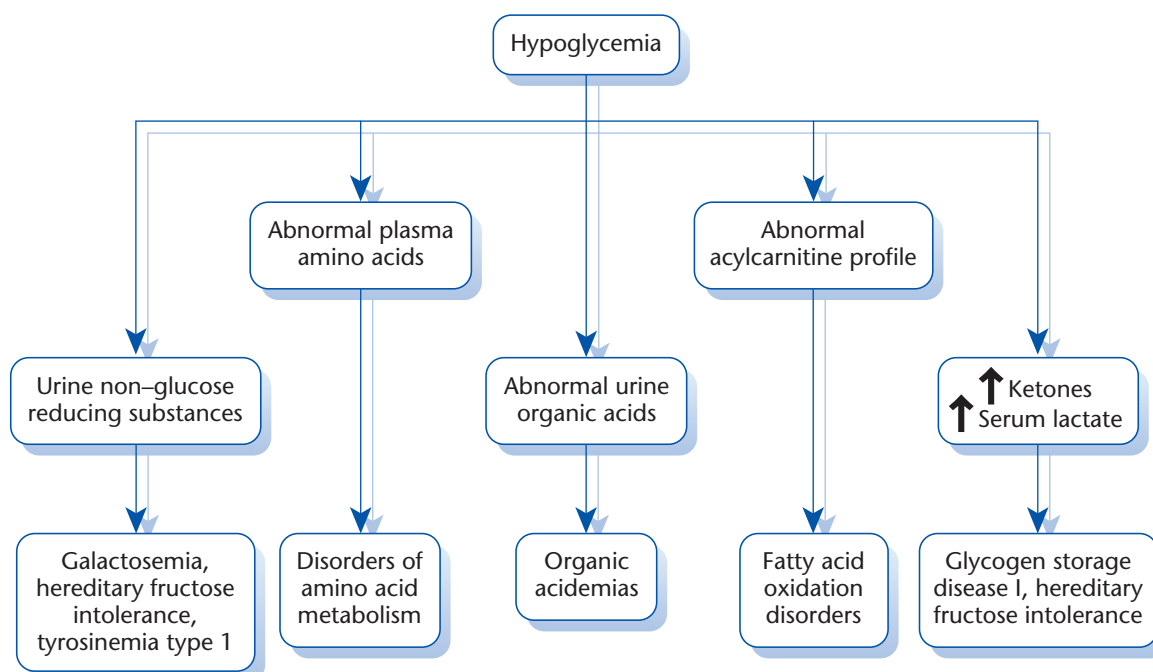

**Figure 106-11** Algorithm for evaluation of hyperammonemia

**Figure 106-12** Algorithm for evaluation of metabolic acidosis

**Figure 106-13** Algorithm for evaluation of hypoglycemia

errors of metabolism presenting with hyperammonemia, metabolic acidosis, and hypoglycemia.

Unfortunately, stressful situations will occur when a newborn infant suspected of having an inborn error of metabolism deteriorates rapidly with impending death before a definitive diagnosis is established. When the physician is presented with this clinical scenario it becomes imperative to establish a diagnosis. Doing so will help the family in 2 major ways: first, by bringing closure to the cause of their baby's death, and second, by providing valuable information for future pregnancies. Table 106-10 provides various samples that should be set aside for future testing. Keep in mind that enzyme activity diminishes rapidly. For proper perimortem sample analysis it is important that the samples are processed rapidly and efficiently with advanced notification of appropriate laboratories. This will ensure that errors in handling will not occur. Consultation with a geneticist is recommended to assist in the ordering and handling of the proper biochemical analysis.

## Chapter 107

THE NEWBORN WITH  
NEUROLOGIC FINDINGS

Oranee Sanmaneechai, MD; Aleksandra Djukic, MD, PhD

*If the infant is pushed slightly and bent forward a few minutes after birth, he will make his first steps. Nevertheless, the newborn is capricious and does not always walk to order. Well disposed at one moment, he is no longer so the next. The examiner is discouraged and gives up; then he tries a last time—the baby starts walking immediately, perfectly regularly and over a long distance.*

—ANDRE-THOMAS AND AUTGAERDEN (1966)

Neurologic examination of the neonate is a complex task; findings depend on age, behavioral stage, and position. Neuronal mechanisms of a newborn are inconsistent, with responses varying from moment to moment. Despite the objective difficulties, when the approach to the neurologically impaired neonate is well thought out and accommodates the individual baby, relevant and reliable information can be obtained (Box 107-1). A thorough knowledge and understanding of the normal development of the infant and young child is fundamental to anyone concerned with the care of children.

The main stages of brain development are illustrated in Figure 107-1. During and after the third trimester of pregnancy, at the time when the fetus becomes viable, all neurons have already migrated to their final destinations. The main developmental events during this period are the following: First, glial cells proliferate in the periventricular germinal zone, which is immature and therefore exquisitely vulnerable. Second, synaptogenesis allows neurons to talk to each other. Insufficiency of synaptic connections is partially the basis of difficulties in the

assessment. The relation between stimulus and response is often not consistent. Third, myelination develops, which will, when the child is older, enable faster and more reliable communication not only between neurons but also between the child and another person. Fourth, apoptosis, or the programmed elimination of neurons that are normally produced in excess, occurs.

A neonate's neurologic organization differs greatly from that of the older child. Initial assessment of the neonate should be based on the following fundamental principles: developmental stage of the infant, assessment adjusted to the expected level of maturity, and differential diagnosis focused on treatable conditions for which a delayed response caused by awaiting consultation with a specialist might alter the prognosis.

## EVALUATION

The goal of evaluation is not only to identify pathologic findings but also to assess the degree of neurologic maturity. This task can be accomplished by careful observation of the quality of spontaneous, endogenously generated movements of the neonate. A rapidly accumulating body of evidence has proved that the spontaneous motility of preterm and term infants, which is in continuity with fetal movements, is of great clinical significance. Spontaneous motility is an important indicator of brain dysfunction at an early age, and it tells us more about the young nervous system than reflex testing. Observation is the most important part of any examination. Expected findings vary with the infant's developmental maturity and may be influenced by in utero environmental conditions such as uteroplacental insufficiency and maternal drug or other exposures, or intrinsic fetal factors, such as brain maldevelopment. The examiner plays an active role in eliciting and quantifying both behavioral and motor responses. Items included in assessment of the preterm and full-term newborn are listed in Box 107-2. The ideal time for the examination is 2 to 3 hours after feeding, when the infant is in a period of quiet wakefulness. Except for lip, glabella, anal, and cremasteric reflexes, which can be elicited regardless of behavioral state, all other reflexes correlate with the level of alertness.

Developmentally, palmar grasp (weak) and Moro reflex (not full) first appear at 28 weeks' (28<sup>0</sup>/<sub>7</sub>–28<sup>6</sup>/<sub>7</sub> weeks)

**BOX 107-1** Neurologic Examination  
of the Neonate**OBSERVATION PERIOD**

- Observation of unprovoked, spontaneous activity
- Qualitative assessment
- Passive role of the examiner

**EXAMINATION PERIOD**

- Response to provoked external stimuli
- Quantitative approach
- Active role of examiner

**Figure 107-1** Main stages of brain development.

**BOX 107-2 Assessment of the Preterm and Full-Term Newborn****EXAMINATION OF THE HEAD**

- Fontanels
- Occipitofrontal (head) circumference
- Skull shape, deformations, and defects
- Evidence of trauma (cephalohematoma, subgaleal hemorrhage, skull depression or deformation, forceps or vacuum injury)

**HABITUATION**

- Light
- Sound

**MOVEMENTS AND TONE**

- Posture
- Arm and leg recoil and traction
- Popliteal angle
- Head control
- Head lag
- Ventral suspension
- Head raising in prone position
- Arm release in prone position

- Spontaneous body movements
- Tremors and startles
- Abnormal body movements

**REFLEXES**

- Deep tendon reflexes
- Palmar grasp
- Rooting
- Sucking
- Walking
- Moro reflex

**NEUROBEHAVIORAL**

- Eye appearance (pupillary light responses, position, movements)
- Auditory and visual orientation
- Alertness
- Defensive reactions
- Irritability
- Consolability

gestation. Deep tendon reflexes are already present at this time. Asymmetrical tonic neck reflex, stepping reflex, and stronger sucking can be recorded from 34 weeks. The healthy term baby has a strong grasp (the infant can be lifted off the bed), full Moro reflex, and placing reflex. The limbs are semiflexed, and the lower limbs are in slight adduction at the hips. When the child is prone, the head may be lifted off the surface and turned to the side. Visual fixation and tracking, which is still not smooth, are present.

**SEIZURES**

*Seizures* are clinical manifestations of temporary alterations in brain function that occur as a result of excessive synchronous neuronal electrical discharge. In the newborn, seizures represent an emergency for 2 main reasons: they indicate significant dysfunction or damage to the immature brain, and they can further interfere with the process of normal neurologic maturation.

The most important single determinant of prognosis in neonates with seizures is their cause. Immediate and thorough investigation for potentially treatable causes and early institution of cause-specific therapy may mitigate the development of long-term sequelae. The initial differential diagnosis is guided by 2 main questions: (1) Is the concerning event epileptic or nonepileptic? (2) If epileptic, then was it provoked? A detailed history and basic laboratory workup are often sufficient diagnostic tools with direct therapeutic implications.

Clinical suspicion that the event is a seizure should be based on the occurrence of paroxysmal, stereotypical, repetitive, and abnormal events. The signs of seizures in the neonate may be different from those in

older children and adults; this difference is the result of the immature state of the central nervous system (CNS) before the final cortical architecture, synaptic networks, and myelination have been attained.

Newborns rarely have well-organized, generalized tonic-clonic seizures; instead, their seizures are characterized by multifocality, asynchrony, disorganized pattern of propagation, and subtle oral-buccal, bicycling, stepping, pedaling, or ocular movements. However, none of the clinical characteristics is specific; based on the characteristics of movements only, events associated with gastroesophageal reflux or those during sleep are often clinically indistinguishable from seizures. Information about the setting in which they occur, reactivity to external stimuli, associated features, and electroencephalographic (EEG) characteristics is more specific.

Nonepileptic events may include jitteriness, characterized by rhythmical tremor as a dominant movement that can be stopped by restraint, is not accompanied by autonomic changes or ocular signs, and is especially sensitive to stimulus. Jitteriness may be caused by hypoglycemia, hypocalcemia, neonatal encephalopathy, or drug withdrawal, but in some cases the cause cannot be determined. Benign neonatal sleep myoclonus occurs only during sleep. The phenomenon disappears spontaneously, and the child's development is normal. Tonic fits associated with gastroesophageal reflux are linked to feeding. Hyperekplexia (familial startle syndrome) is characterized by abnormal response to unexpected stimuli associated with sustained tonic spasms or exaggerated startle with additional generalized hypertonia.

The main causes of epileptic seizures include hypoxia-ischemia, intracerebral hemorrhage, brain

**BOX 107-3 Main Categories of Neonatal Hypotonia****PERIPHERAL OR MOTOR UNIT HYPOTONIA**

- Muscle diseases (congenital myopathies, congenital muscular dystrophies, myotonic dystrophy)
- Neuromuscular junction diseases (transient neonatal myasthenia gravis, congenital myasthenic syndrome, infantile botulism)
- Peripheral nerve diseases (hereditary motor and sensory neuropathies)
- Anterior horn cell disease (spinal muscular atrophy)

**CENTRAL HYPOTONIA**

- Brain and spinal cord (acute injuries or congenital)
- Chromosomal disorders (Down syndrome, Prader-Willi syndrome, other genetic syndromes)

**METABOLIC OR ENDOCRINE DISORDERS**

- Metabolic disorders (amino acid, organic acid, lactic acid, glycogen storage disorder, mitochondrial disorders)
- Endocrine disorders (hypothyroidism)

infarction, metabolic disorders (ie, hypoglycemia, hypomagnesemia, hypocalcemia), infection, inborn error of metabolism, congenital malformation, genetic predisposition, neonatal abstinence syndrome from in utero drug exposure, and pyridoxine dependency. An important point to keep in mind is that several factors may contribute to the onset of seizures in a single infant. Because most neonatal seizures occur in a provoked setting, when the provocative factor is corrected, they are usually short lived.

Benign familial and nonfamilial neonatal seizures are neonatal epileptic syndromes defined by a favorable outcome. The classic phenotype of benign familial seizures is a neonate born after an uneventful pregnancy and delivery with onset of tonic-clonic seizures during the first 2 weeks of life, intact neurologic function between seizures, and a family history of seizures (autosomal-dominant inheritance). In the absence of family history and an identifiable cause, when seizures in an otherwise healthy neonate appear between 3 and 7 days of age (*fifth-day fits*), diagnosis of benign neonatal nonfamilial convulsions can be proposed. The interictal EEG pattern is either normal or moderately altered. Both syndromes can only be diagnosed after excluding provocative factors.

Early infantile epileptic encephalopathy and early myoclonic encephalopathy are severe neonatal epilepsies characterized by onset during the first days or weeks of life, severe seizures that do not respond to medication, a burst-suppression EEG pattern, and a poor prognosis.

In addition to the laboratory tests that should be performed urgently (determination of blood glucose, sodium, potassium, calcium, phosphorus, and magnesium levels; lumbar puncture), the workup includes EEG and imaging studies. Magnetic resonance imaging is preferable for detecting possible abnormal structural brain malformations and anomalies. The need for further, more extensive workup is determined by the results of the initial tests.

Clinical observations and the precise characterization of neonatal seizures form the basis for their rational evaluation and therapy. Treatment strategy and duration should be based on the cause and severity of seizures. Treatment based on the specific cause of seizures should always be considered first. The initial antiepileptic medications are phenobarbital followed

by phenytoin and diazepam. Duration of treatment depends on the etiology. It is short term for a provoked seizure or benign neonatal seizure. Medications are usually provided for 2 to 3 months. Long-term antiepileptic medication is needed for the severe epileptic syndromes or congenital cerebral malformations.

## DISORDERS OF MUSCLE TONE AND MOVEMENT

*Tone* refers to resistance of skeletal muscles to passive movement and also to muscle tension at rest. Tone deficiency, or *hypotonia*, is among the most common neurologic signs in the neonate. It can be caused by a dysfunction at any level of the nervous system, from the muscles to the cortex of the brain, and it can result from drugs administered to the mother (benzodiazepines) or from genetic or metabolic disorders (Box 107-3). Initial assessment that focuses on the presence or absence of reflexes, weakness, associated systemic signs, and dysmorphic features is helpful. Based on the combination of answers to these simple questions, planning of further workup and treatment can be approached.

In primary disorders of the muscle (congenital myopathy, congenital muscular dystrophy, myotonic dystrophy), neonates are hypotonic, weak, and typically areflexic.

Congenital myopathies are a group of primary muscle diseases with abnormalities of muscle structure or function. They present with hypotonia, weakness, and facial muscle weakness. Muscle biopsy can help to identify the presence of abnormal muscle structures such as central core, nemaline rod, and centronuclear. Genetic testing for many of these conditions is available.

Congenital muscular dystrophies present with muscle weakness, respiratory difficulty, and contractures, with variable involvement of the eyes, brain, and other tissues. Patients with these conditions have high creatine kinase and dystrophic muscle, with signs of muscle necrosis and regeneration on biopsy.

Myotonic dystrophy is an autosomal-dominant condition and a cause of neonatal hypotonia. Family history of myotonic dystrophy or maternal signs of disease such as myotonia are clues to diagnosis. The definite diagnosis can be made by genetic testing.

Testing should be done in the event of unexplained hypotonia because the disorder might not have been diagnosed yet in the family. These diseases are chronic, and the care in the neonatal period is supportive.

Neuromuscular junction disorders, including infant botulism and transient neonatal myasthenia gravis, are treatable but potentially life-threatening disorders. Therefore, the physician needs to recognize the symptoms of these conditions early.

Myasthenic infants are hypotonic and weak, although their deep tendon reflexes are present. Transient neonatal myasthenia gravis occurs in 10% to 15% of infants born to myasthenic mothers as a result of transplacental transfer of circulating acetylcholine receptor antibodies from the mother to the fetus. The severity of the mother's disease has no relationship to the severity of the neonate's disease. Symptoms typically appear within the first day of life with hypotonia, feeding difficulties, trouble breathing, feeble cry, facial weakness, and oculomotor problems. Diagnosis is confirmed by positive antibodies to acetylcholine receptor, repetitive nerve stimulation test, and clinical response to anticholinesterase medications. The condition is self-limited; it completely resolves within a few weeks and does not recur. Treatment is supportive, with anticholinesterase inhibitors.

Congenital myasthenic syndromes represent a heterogeneous group of nonautoimmune diseases caused by genetic defects that affect neuromuscular transmission. They are typically of autosomal-recessive inheritance. Response to anticholinesterase inhibitors is variable. A classification system of congenital myasthenic syndromes based on molecular genetics is established.

Botulism occurs when ingested spores of *Clostridium botulinum* colonize and grow in the infant's large intestine and produce botulinum neurotoxin. It causes constipation, weakness (notably of gag, cry, suck, and swallow), ptosis, autonomic (pupillary) abnormalities, loss of muscle tone, and difficulty breathing. Symptoms typically appear between 18 and 36 hours after the infant is infected by the bacteria and between 3 weeks and 6 months of life. A human-derived botulism antitoxin, intravenous botulism immunoglobulin, is a safe and effective treatment that has been licensed by the US Food and Drug Administration as Baby-BIG. Treatment should be provided as soon as possible because its efficacy may decrease over time as motor nerve intoxication proceeds.

Spinal muscular atrophy is among the most common neuromuscular disorders in childhood; it is progressive. Pathologically, spinal muscular atrophy is characterized by degeneration of anterior horn cells of the cord and of the bulbar motor nuclei. This disorder has autosomal-recessive inheritance. The affected infants are hypotonic, weak, and areflexic. They have trouble breathing as a result of weakness of their intercostal muscles, and they have feeding difficulty. Cognition and facial expression are normal. In spinal muscular atrophy type I, which has its onset before 6 months of age, the infant has no ability to sit and rarely survives beyond the first 2 years of life. A genetic blood test confirms diagnosis and should be performed early to guide the family appropriately.

In severely hypotonic infants with paraplegia and urinary retention, spinal cord injury should be

screened for with imaging studies in the appropriate clinical setting.

Genetic or syndromic conditions in a hypotonic infant are considered based on dysmorphic features, systemic signs, presence of deep tendon reflexes, and often absence of weakness. Neonatal hypotonia or floppiness at birth in an infant with weak cry and decreased activity are highly suggestive of Prader-Willi syndrome (PWS). This disorder occurs in 1 in 10,000 to 15,000 live births and should be considered in any neonate who exhibits generalized hypotonia. Infants with PWS often have a history of breech or other abnormal presentation, decreased or atypical fetal movement patterns, excessive sleepiness, poor sucking reflexes, and feeding difficulties in the newborn period. Profound hypotonia may lead to severe respiratory compromise. Other common features include a weak cry and genital hypoplasia (cryptorchidism, small penis, scrotal hypoplasia, small labia minora, and clitoral hypoplasia). PWS is caused by deletions on the paternal chromosome 15, uniparental disomy of the maternal chromosome 15, and, rarely, imprinting defects. Molecular genetic testing is required to confirm the diagnosis.

Some hypotonic infants have CNS disorders, and in these cases hypotonia is accompanied by other signs of CNS involvement, such as lethargy or seizures. Decrease in muscle tone is an immediate response to severe CNS injury. Increased tone is a delayed consequence. Therefore hypertonia, which is a common neurologic problem in children, is far less common in neonates. Acute CNS injury of any cause (vascular, metabolic, infectious) can cause a depression of nervous functions during the initial phase. Motor responsiveness improves, and an increase in tone develops over the course of weeks.

*Hypertonia* refers to increased resistance to passive movement and is caused by a lesion between the cerebral cortex and the anterior horn cells at the level of the spinal cord. The syndrome of upper motor-neuron dysfunction consists of increased muscle tone, weakness, and hyperreflexia.

Hypoxia-reperfusion injuries to the brain in both preterm and term infants are among the main causes of upper motor neuron syndrome. Interestingly, the same pathophysiologic event that causes similar long-term consequences also causes different types and patterns of cellular injury at different ages. Selective neuronal necrosis that is most prominent in the watershed areas is the pathologic substrate in the term neonate. Lesions in a periventricular distribution in the white matter are also caused by hypoxia and reperfusion in the preterm baby. Therefore, topographic distribution of the weakness and hypertonia varies according to the site, extent of injury, and age of the infant. These injuries typically develop in the form of either hemiplegia or quadriplegia in the term neonate and diplegia in the preterm neonate. One of the etiologies of static encephalopathy, spastic quadriplegia, or cerebral palsy is a neonatal hypoxic ischemic encephalopathy (HIE), an acute encephalopathy caused by cerebral ischemia and hypoxemia, which result from perinatal asphyxia. Clinical presentation of HIE includes encephalopathy, seizures, hypotonia, or hypertonia. Treatment of HIE is mainly supportive. Selective head cooling (by cool cap) is a novel and promising treatment approved by the US

Food and Drug Administration in January 2009 for treatment of the full-term infant with moderate to severe HIE. Selective brain hypothermia (temperature 34.5°C) during the period between 6 and 72 hours of age slows the metabolism and reduces energy requirements, acting through a neuroprotective effect. About 75% to 96% of infants with severe HIE have neurologic disabilities, including spastic quadriplegia, cognitive deficit, seizure, hearing loss, and death. Therapeutic hypothermia has been found to improve mortality and morbidity in these patients. Brain cooling is done in the hospital by a neonatologist using complex instruments, continuous monitoring, and close assessment of various organ systems, but not all hospitals in the United States have these facilities. Family physicians caring for future mothers specifically at risk to give birth to an infant with asphyxia should be aware of their regional brain cooling centers. Mothers at risk for having a newborn with severe HIE who might benefit from hypothermia treatment are those with chronic systemic disease resulting in uteroplacental insufficiency, placenta previa, or abruptio placenta. Prompt evaluation and immediate treatment are crucial to reduce morbidity and mortality and to facilitate optimal development of the infant.

Cerebrovascular accidents (ischemic or hemorrhagic) lead to focal brain lesions and focal, lateralized signs of upper motor dysfunction such as hemiparesis. Contrary to the acute and catastrophic presentation of stroke in older children and adults, many neonates follow a different clinical scenario. They have normal neonatal neurologic history and may remain asymptomatic during the first few months of life. Development of early hand preference during the first year of life or seizures (or both) is usually the first sign of their impairment. The pediatrician should initiate a thorough neurologic evaluation of these infants immediately. Most neonatal strokes are arterial in origin, but they can also result from sinovenous thrombosis, coagulation abnormalities, certain genetic mutations, perinatal complications, or cardiac anomalies. Neonates with stroke usually have more than 1 risk factor. The overall risk for recurrence is low.

Germinal matrix intraventricular hemorrhage and periventricular leukomalacia is the brain injury that occurs in premature infants. Its occurrence is inversely related to gestational age and birth weight. Primary injury and destruction of the glial precursors have a direct influence on the subsequent stages of brain maturation. Accelerated cell death of these reversibly injured neurons occurs through a variety of secondary injury mechanisms (excitotoxicity, oxidative stress, inflammation) and is a potential therapeutic target.

Feeding difficulties occur in a variety of clinical settings. They may be caused by encephalopathies of different causes; disorders of the anterior horn cell, neuromuscular junction, or muscles; congenital malformations (Möbius syndrome, Chiari malformation); focal posterior fossa tumors; or laryngeal paralysis. Congenital isolated pharyngeal dysfunction is a self-limited disorder that is diagnosed by exclusion; it can be severe and may persist for months.

Decreased arm movement and asymmetrical Moro reflex are commonly caused by *brachial plexus injury*. Risk factors for brachial plexus injury include large babies, shoulder dystocia, and breech delivery.

Erb palsy (cervical roots 5 and 6) is the most common form and exhibits with the arm being adducted, pronated, and internally rotated as a result of weakness of the shoulder abduction, elbow flexion, and supination. Grasp is usually present. Klumpke paralysis (C7, C8, T1) results in weakness of the hand muscles, absent grasp, and sometimes Horner syndrome. Total brachial plexus palsy involves both upper and lower roots. The site and type of nerve injury determine the prognosis. Most patients have the least severe form of nerve injury (neurapraxia) and recover spontaneously or with supportive physical therapy. Treatment includes occupational or physical therapy and is directed toward prevention of contractures. Avulsion, the most severe form of the injury, is rare. Surgical exploration should be considered in infants who do not experience sufficient recovery within 3 months.

## **INJURIES OF THE HEAD AND SKULL**

Caput succedaneum, cephalohematoma, and linear fractures are rarely associated with intracranial disease and are self-limited. *Ping-pong fracture* is a form of depressed skull fracture associated with inward buckling of the bone, often without a fracture line. It is rarely associated with intracranial injuries and can often be corrected by nonsurgical techniques (eg, vacuum extractor, breast pump).

Potentially dangerous and treatable conditions are growing skull fracture and subgaleal hemorrhage. Growing skull fractures result from tearing of the dura and trapping of arachnoid and brain tissue in the fracture. The pulsatile force of the brain during its maximal growth causes the fracture in the thin skull to enlarge. These fractures commonly produce a progressive, often pulsatile, scalp mass that appears some time after head trauma during infancy. Imaging is diagnostic. Surgery is required to repair the dural tear.

Subgaleal hemorrhage is a rare but potentially lethal condition found in newborns. It is caused by accumulation of the blood between the epicranial aponeurosis of the scalp and the periosteum. Because this space may hold a significant volume, subgaleal hemorrhage can lead to severe hypovolemia, which may result in death. The swelling, which appears as a fluctuant, boggy mass over the scalp, develops gradually 12 to 72 hours after delivery. Subgaleal hemorrhage is most often associated with vacuum extraction and forceps delivery. Treatment consists of prompt and aggressive prevention of hypovolemic shock and treatment of any associated coagulopathy.

**Chapter 108****SURGICAL EMERGENCIES OF THE CHEST AND ABDOMEN IN THE NEWBORN**

*Anna Christina Ganster, MD; Mohamed Farooq Ahamed, MD; Mamta Fuloria, MD*

**INTRODUCTION**

Newborns often present with nonspecific gastrointestinal (GI) signs that can indicate either GI pathology or infection. Therefore, an understanding of the common presenting GI signs and their differential diagnoses, as well as diagnostic work-up and management, is essential when caring for neonates.

**GENERAL APPROACH TO A NEWBORN WITH SUSPECTED ABDOMINAL PATHOLOGY****History**

Since infants with GI pathology often present within the first few days after birth, the postnatal history is not always contributory. Valuable information can be obtained from the prenatal history and any antenatal testing that was performed. Specific attention should be paid to prenatal findings such as oligohydramnios or polyhydramnios which can indicate genitourinary or GI abnormalities. Results from prenatal ultrasound examinations are usually readily available and can guide the postnatal diagnostics and management. (See Chapter 97, Postnatal Assessment of Common Prenatal Sonographic Findings.)

Monitoring urine output and stooling patterns is routine during the first days of life; additionally, parents should be encouraged to monitor voids and stools even after the infant is discharged home. Feeding patterns and difficulties with oral intake should be evaluated, especially in infants presenting with symptoms such as emesis, abdominal distention or delayed passage of stool. It is also important to assess the infant for nonspecific signs such as activity level or presence of lethargy or temperature instability, whether the infant wakes for feedings, the quality of the infant's suck and muscle tone, and for signs of respiratory distress or pain. Although the presence of these symptoms/signs can suggest GI pathology, they are not specific for GI involvement and other conditions such as sepsis should be considered in the differential diagnosis and ruled out. These signs can also be indicative of thoracic- or otorhinolaryngology-related pathology.

**Physical Examination**

In addition to a general physical examination, special attention should be paid to assessment of the abdomen in newborns presenting with feeding intolerance, emesis, abdominal distention, GI bleeding, or delayed passage of stool. Specifically, the examination should start with inspection of the abdomen with the infant in the

supine position. In addition to noting generalized versus more focal distention, prominent abdominal veins, or discoloration and abnormalities of the umbilicus may be appreciated. Although nonspecific, the presence of hyperactive bowel sounds (indicative of acute obstruction) or absence of bowel sounds (indicative of ileus) can be helpful clues on auscultation. Unlike in older children, percussion is often not helpful in the neonatal period. Palpation should start from the lower quadrants so as not to miss the lower edges of the liver or spleen. Tenderness can be appreciated by carefully observing the infant during palpation. A soft, nontender abdomen can be reassuring but does not necessarily exclude pathology. The location and characteristics of masses should be noted. Inspection of the inguinal and perianal area and exterior genitalia, as well as a rectal examination, should also be performed.

**Common Presenting Symptoms**

The most common presenting symptoms observed in infants with abdominal pathology include feeding intolerance with or without emesis (Figure 108-1), abdominal distention (Figure 108-2), delayed passage of stool (Figure 108-3), and abdominal pain/discomfort (see Table 108-1 for a clinical tool to assess neonatal pain). (See also Chapter 124, Abdominal Distention, Chapter 125, Abdominal Pain, Chapter 206, Vomiting, and Chapter 257, Gastrointestinal Obstruction.)

In the following sections, some of the more common GI disorders that occur in neonates are described, including pathogenesis, clinical findings, diagnostic tests, and management.

**ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA**

Esophageal atresia (EA; complete interruption in the continuity of the esophageal lumen) and tracheoesophageal fistula (TEF; fistulous connection between the proximal or distal esophagus and the airway) are common congenital anomalies occurring in 1 in 2,500 to 4,500 births. The most common form is EA with a distal TEF (88% of cases), where the upper esophagus ends in a blind pouch and the TEF is connected to the distal esophagus. Figure 108-4 depicts the various types of TEF.

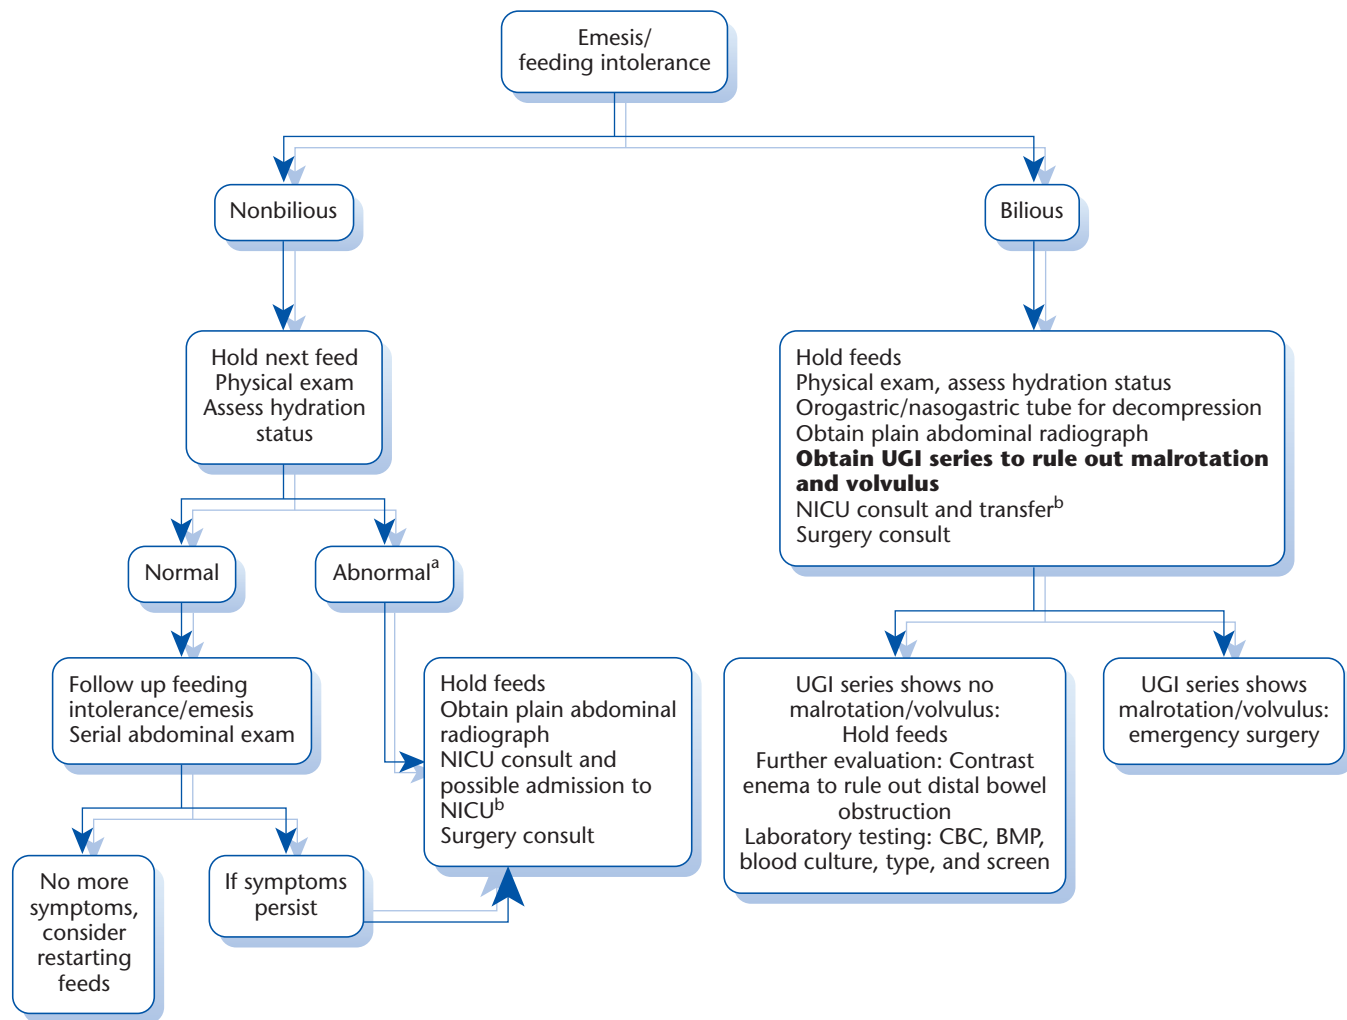

**Etiology and Genetics**

The etiology of EA and TEF is thought to be multifactorial, and most cases are sporadic and nonsyndromic. However, EA and TEF are often associated with other congenital anomalies including cardiac (35% of patients), genitourinary, GI, skeletal, and CNS defects. EA/TEF is commonly seen in patients with VACTERL association (*vertebral, anal, cardiac, tracheoesophageal, renal, and limb*), DiGeorge and Down syndrome, Pierre-Robin sequence, and CHARGE association (*coloboma, heart anomalies, atresia of the nasal choanae, retardation of growth and/or development, and genital and ear anomalies*).

**Diagnosis and Management**

The prenatal diagnosis of EA may be suggested by the presence of polyhydramnios and the absence of

**Figure 108-1** Management of infants with emesis and feeding intolerance. NICU, neonatal intensive care unit; UGI, upper gastrointestinal; CBC, complete blood count; BMP, basic metabolic panel.

<sup>a</sup>Abnormal exam: abdominal distention, abnormal bowel sounds, tenderness, abdominal wall edema or erythema, assess for inguinal hernia.

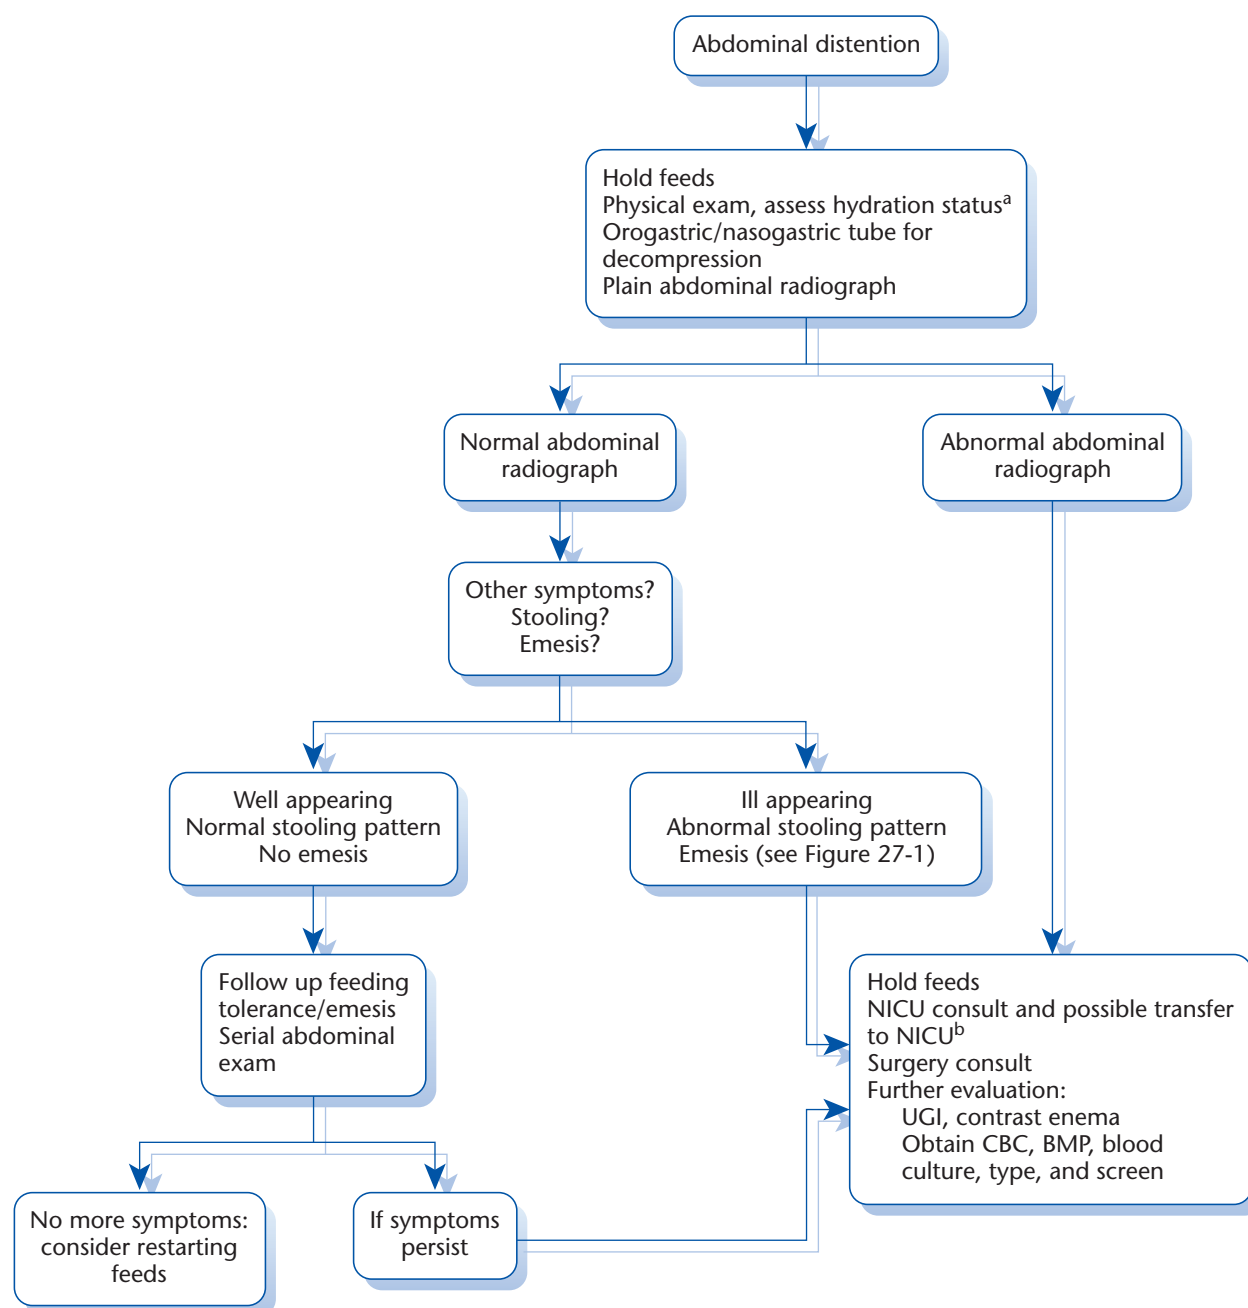

<sup>b</sup>If patient is at a facility with no pediatric surgery or neonatal/pediatric intensive care, consider early transfer to such a facility for further evaluation and management. If patient is ill-appearing, establish IV access and start IV fluids and antibiotics until transport can be arranged.

the stomach bubble on fetal ultrasound. However, most cases of EA and TEF are diagnosed in the newborn period. The typical presentation includes the presence of copious oropharyngeal secretions, feeding intolerance, reproducible choke and spit with every swallow, cyanosis, and respiratory distress. Children with isolated TEF without EA (“H-type” fistula) often present after the neonatal period with chronic respiratory difficulties such as paroxysms of coughing precipitated by feeding, gaseous distention of the GI tract, recurrent pneumonia, and bronchospasm.

The diagnosis is made by the careful passage of an 8-10 French nasogastric/orogastric tube, followed by radiographs of the chest and abdomen to ascertain tube position. Passage of the tube nasally can also help rule out choanal atresia. In patients with EA, the orogastric tube typically stops at 10 to 12 cm

(in the proximal esophageal pouch) (Figure 108-5 and Figure 108-6); the presence of a gas-filled stomach and intestine indicates the presence of a distal TEF (Figure 108-6).

Infants with EA or TEF should be evaluated for other congenital anomalies. Preoperative echocardiography is essential to define the anatomy of the aortic arch and its relation to the trachea and esophagus, as well as to diagnose any cardiac abnormalities that may be important predictors of morbidity and mortality. The newborn may experience significant respiratory distress caused by either marked abdominal distention that pushes the diaphragms up and limits respiratory excursions or aspiration of secretions and reflux of gastric contents into the lung through the fistula. A repleg/sump tube should be carefully placed into the proximal esophageal pouch

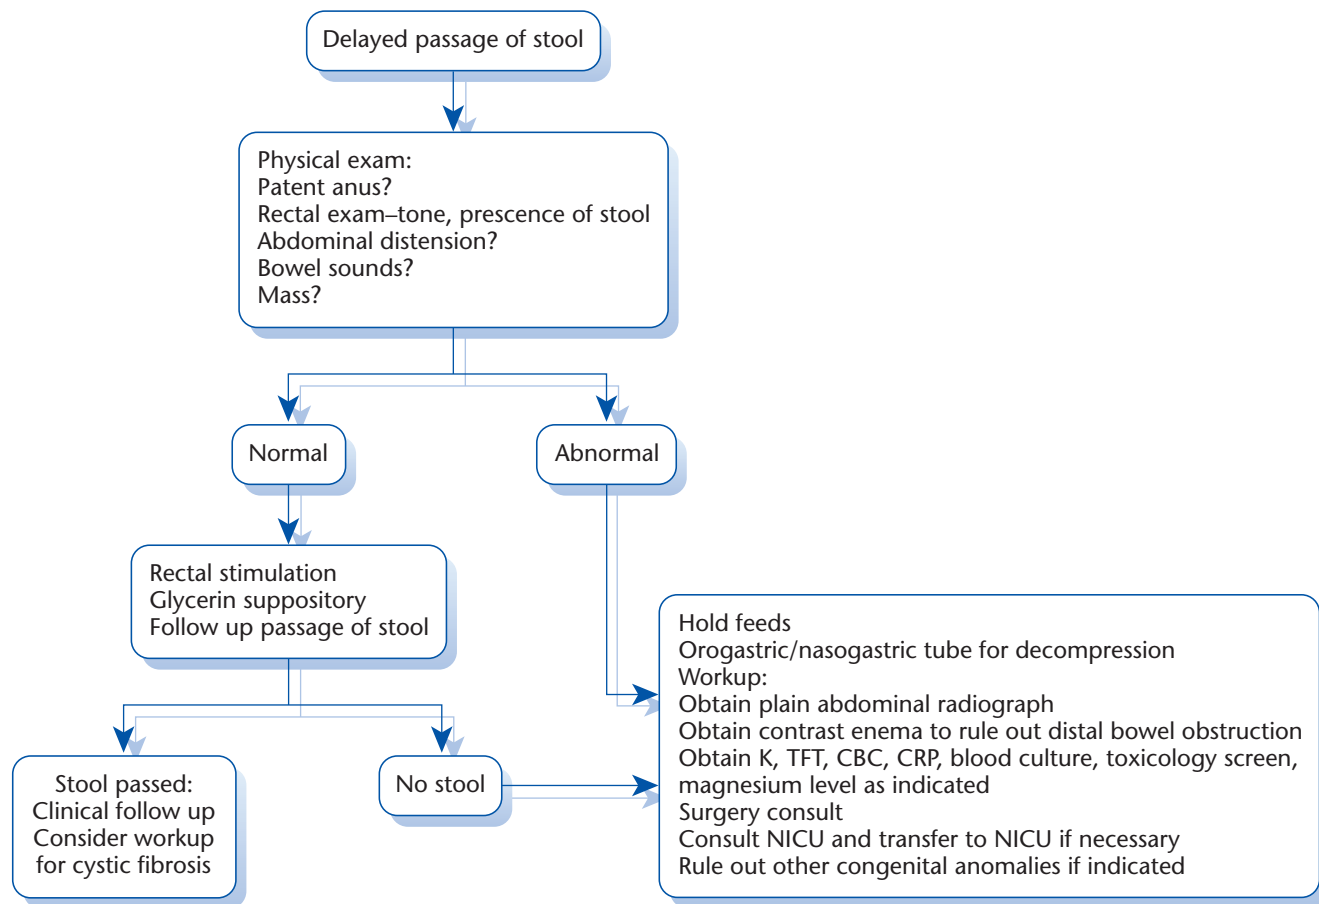

**Figure 108-2** Management of infants with abdominal distention. NICU, neonatal intensive care unit; UGI, upper gastrointestinal; CBC, complete blood count; BMP, basic metabolic panel.

<sup>a</sup>Abnormal exam: abdominal distention, abnormal bowel sounds, tenderness, abdominal wall edema, abdominal wall erythema, assess for inguinal hernia.

<sup>b</sup>If patient is currently at a facility with no pediatric surgery or neonatal or pediatric intensive care unit, consider early transfer to such a facility for further management. If patient is ill-appearing, establish IV access and start IV fluids and antibiotics until transport can be arranged.

and connected to suction (40 mm Hg). The head of the bed should be elevated to 45 degrees to avoid gastric reflux as much as possible. Preoperative intubation and use of continuous positive airway distending pressure (CPAP) should be avoided if possible as positive airway pressure can lead to significant gastric distention

via the TEF and can therefore compromise ventilation even further. If intubation becomes necessary, the endotracheal tube should be placed just proximal to the carina as most fistulas are located above the carina. Prophylactic antibiotic treatment should be considered in these patients.

**Figure 108-3** Management of infants with delayed passage of stool. *NICU*, neonatal intensive care unit; *CBC*, complete blood count; *K*, potassium; *TFT*, thyroid function panel; *CRP*, C-reactive protein. If patient is currently at a facility with no pediatric surgery or neonatal or pediatric intensive care unit, consider early transfer to such a facility for further management. If patient is ill-appearing, establish IV access and start IV fluids and antibiotics until transport can be arranged.

The operative repair of EA or TEF usually consists of division of the fistula and primary anastomosis of the distal and proximal esophageal pouches. In cases where the gap between the 2 ends is deemed too far apart for primary anastomosis, gastrostomy tube placement and delayed primary anastomosis at 8 to 12 weeks of age may be appropriate. In cases with “long-gap” atresia, either serial dynamic lengthening of the esophagus or replacement of the esophagus at a later age (3–4 months) is performed. At present, gastric transposition for esophageal replacement is preferred by many surgeons.

### Complications and Outcomes

GI complications are common sequelae following EA or TEF repair. Anastomotic leaks complicate the early postoperative course in 10% of patients. Most are minor and seal spontaneously. Esophageal strictures develop in up to 40% of infants and should be considered in the differential diagnosis of children with history of EA or TEF who present with dysphagia, poor feeding, emesis, food aspiration, and recurrent aspiration pneumonitis. Most patients with strictures have good results with repeated dilation; the need for esophageal dilation

decreases with increasing age of the patient. Both anastomotic leak and gastroesophageal reflux disease (GERD) are related to the development of strictures. Abnormal peristalsis is found in almost all children with EA or TEF. Because of the intrinsic motor dysfunction of the esophagus, GERD is extremely common in patients with EA/TEF; long-standing and severe GERD can lead to subsequent development of esophagitis. Approximately half of children with GERD will respond to medical therapy; however, as many as 25% of patients eventually require surgical management of GERD (Nissen fundoplication). Recurrence of GERD after surgery occurs in up to 25% of children. Dysphagia related to dysmotility is common and can persist into adulthood. Children will often need to eat slowly, take plenty of fluids with meals, and avoid certain foods (such as meats and doughy baked goods). In severe cases, infants may present with failure to thrive, which can be a result of both dysphagia and GERD. Respiratory symptoms are almost as common as GI symptoms, especially in the first 3 years of life, and are important contributors to hospitalization and late mortality. Recurrent pneumonia, chronic cough, and bronchitis seem to decrease

**Table 108-1** Neonatal Pain, Agitation, and Sedation Scale (N-PASS)

ASSESSMENT	SEDATION		SEDATION/ PAIN	PAIN/AGITATION	
Criteria	-2	-1	0/0	1	2
<b>Crying/ Irritability</b>	No cry with painful stimuli	Moans or cries minimally with painful stimuli	No sedation/ No pain signs	Irritable or crying at intervals Consolable	High-pitched or silent-continuous cry Inconsolable
<b>Behavior State</b>	No arousal to any stimuli No spontaneous movement	Arouses minimally to stimuli Little spontaneous movement	No sedation/ No pain signs	Restless, squirming Awakens frequently	Arching, kicking Constantly awake or arouses minimally/ no movement (not sedated)
<b>Facial Expression</b>	Mouth is lax No expression	Minimal expression with stimuli	No sedation/ No pain signs	Any pain expression intermittent	Any pain expression continual
<b>Extremities/ Tone</b>	No grasp reflex Flaccid tone	Weak grasp reflex ↓ muscle tone	No sedation/ No pain signs	Intermittent clenched toes, fists, or finger splay Body is not tense	Continual clenched toes, fists, or finger splay Body is tense
<b>Vital Signs: HR, RR, BP, SaO<sub>2</sub></b>	No variability with stimuli Hypoventilation or apnea	<10% variability from baseline with stimuli	No sedation/ No pain signs	↑ 10%–20% from baseline SaO <sub>2</sub> 76%–85% with stimulation—quick recovery	↑ 20% from baseline SaO <sub>2</sub> ≤75% with stimulation—slow recovery Out of sync with vent

**Figure 108-4** Different types of TEF. Type A: Esophageal atresia without TE fistula. Type B: Esophageal atresia with a fistulous connection between the proximal esophageal pouch and the trachea. Type C: Esophageal atresia with a fistula between the distal esophageal pouch and the trachea, blind proximal pouch (most common type). Type D: Esophageal atresia with a fistula between both the proximal and distal esophageal pouches and the trachea. Type E: H-type TE fistula (no esophageal atresia).

**Figure 108-5** Esophageal atresia without tracheoesophageal fistula. Note orogastric tube ending in esophageal pouch and absent bowel gas indicating no fistulous connection to the distal part of the esophagus.

over time, whereas the prevalence of wheezing remains fairly constant until early adulthood. Tracheomalacia, although often found on pathology specimens, seems to be clinically significant in only 10% of patients. If persistent and recurrent respiratory symptoms and choking/gagging with feeds occur, the recurrence of TEF should be considered and ruled out.

## CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia (CDH) is a condition where there is herniation of the abdominal viscera into the thoracic cavity through a defect in the diaphragm. It occurs in 1 in 2,200 to 4,000 live births and is often associated with other congenital malformations.

### Etiology and Pathophysiology

The diaphragm initially develops as a septum between the heart and liver, progresses posterolaterally, and closes at the left foramen of Bochdalek at approximately 8 to 10 weeks' gestation. Failure of closure of the pleuroperitoneal canals during embryonic development of the pleural and peritoneal cavities results in CDH. The defects in the diaphragm can be posterolateral or central, resulting in Bochdalek and Morgagni hernias, respectively. Approximately 85%

**Figure 108-6** Esophageal atresia with distal tracheoesophageal fistula. Note curled orogastric tube in proximal pouch and the presence of bowel gas.

of CDH are left sided; in these patients, there can be herniation of the small or large bowel and other solid intra-abdominal organs. Fourteen percent of CDH are right-sided; in these patients, the liver and a portion of the large bowel are present in the thoracic cavity. Bilateral CDH is rare, occurring in approximately 1% of cases, and is usually fatal. The incidence of associated congenital anomalies varies depending on the method of diagnosis and inclusion of autopsy cases/aborted fetuses. Anomalies described in patients with CDH include chromosomal anomalies (trisomy 13, 18, 21), Fryns syndrome, congenital heart disease (hypoplastic left heart syndrome, coarctation of the aorta, and tetralogy of Fallot), neural tube defects, and cleft palate.

The herniated abdominal contents result in compression of the developing lungs with subsequent development of pulmonary hypoplasia and hypertrophy of the pulmonary vascular smooth muscle cells. Both lungs are affected with the ipsilateral lung being more affected than the contralateral lung. The degree of pulmonary hypoplasia depends on the size of the defect, presence of liver in the thoracic cavity, and gestational age at which the hernia occurred. After birth, these changes interfere with gas exchange leading to respiratory failure and pulmonary hypertension.

### Diagnosis and Management

Approximately 50% to 60% of patients with CDH are diagnosed antenatally. The clinical presentation varies, with minimal respiratory symptoms in patients

with small hernias and severe respiratory failure in patients with large hernias and associated pulmonary hypoplasia or pulmonary hypertension. The abdomen may be scaphoid with poor air entry on auscultation. Heart sounds may be shifted to the right in patients with left-sided hernias. Chest radiography will reveal loops of bowel in the thoracic cavity (Figure 108-7). If the stomach is herniated into the thoracic cavity, the tip of the OG tube may be seen curling in the left side of the chest (Figure 108-8).

If antenatally diagnosed, patients with CDH should be delivered at a tertiary care center with a neonatal intensive care unit equipped with extracorporeal membrane oxygenation (ECMO) and pediatric surgical capabilities. If the diagnosis of CDH is known or suspected, infants should be intubated immediately after birth and an orogastric tube placed for gastric decompression. The use of face mask to provide positive pressure ventilation should be avoided. Gentle ventilation strategies with permissive hypercapnia should be adopted to minimize lung injury. High-frequency ventilation may be required in patients in whom acceptable blood gas parameters cannot be achieved with conventional modes of ventilation. ECMO is used as rescue therapy in cases of persistent or worsening hypoxemia and failure of ventilatory strategies. Routine use of surfactant is not recommended; however, it may be beneficial in preterm infants with respiratory distress syndrome. Although there may be short-term benefit from the selective use of inhaled nitric oxide (iNO) therapy, the routine use of iNO for all CDH infants is not supported by the available data. Surgical repair should preferably be

delayed until the patient is stable and pulmonary hypertension has resolved. Surgery involves reduction of the viscera and closure of the defect in the diaphragm. The approach is determined by the size of the defect, with large defects requiring a patch for closure and small defects being closed either primarily or with a patch.

### Complications and Outcomes

Antenatal diagnosis of CDH is associated with poor prognosis. Antenatal ultrasonographic and magnetic resonance imaging (MRI) findings associated with increased mortality include presence of the liver in the thorax, low lung-to-head ratio (LHR) and total fetal lung volume, small lung-to-thorax transverse area ratio, low gestational age at diagnosis, mediastinal shift, left heart hypoplasia, and stomach in the thorax. Postnatal factors associated with poor prognosis are low Apgar score at 5 minutes, the size of the diaphragmatic defect, low birth weight, right-sided defect, the need for ECMO, surgical repair performed while patient is on ECMO, and persistence of pulmonary hypertension beyond 3 to 4 weeks of age.

Survival of patients with isolated CDH is approximately 70% if ECMO is required and 90% if ECMO is not needed. Mortality and morbidity in CDH patients with other severe congenital anomalies is dependent, at least in part, on these associated abnormalities. Long-term complications include pulmonary hypertension, obstructive airway disease, and GERD with failure to thrive. Pulmonary hypoplasia and pulmonary hypertension predispose children with CDH

**Figure 108-7** Congenital diaphragmatic hernia. Note bowel loops in the left hemithorax with mediastinal shift to the right.

**Figure 108-8** Congenital diaphragmatic hernia. Note that the stomach bubble is in the left hemithorax with the tip of the orogastric tube coiled in the stomach.

to a high risk for hypoxemia, which may result in neurodevelopmental delays. Chest wall deformities and scoliosis may also be seen.

### INTESTINAL ATRESIA/STENOSIS

Intestinal atresia is the most common cause of congenital intestinal obstruction. Approximately one-third of bowel obstructions in the newborn period can be attributed to intestinal atresia, with an overall incidence of 1 in 2,700 births. Duodenal atresia and stenosis are slightly more common than jejunoileal atresia, whereas colonic atresias are rare.

#### Etiology and Genetics

Duodenal obstruction is thought to be caused by a failure of recanalization of the duodenal lumen from its solid cord stage, leading to either partial obstruction by an imperforate membrane or mucosal web or complete atresia. More than 50% of cases are associated with other congenital anomalies such as cardiac, GI (pancreatic anomalies, intestinal malrotation, esophageal atresia, Meckel diverticulum, or imperforate anus), central nervous, and renal anomalies. Approximately 30% of patients with duodenal atresia have Down syndrome (trisomy 21). Other associated genetic abnormalities include Feingold syndrome and a variant of the VACTERL association. In contrast, jejunoileal atresia is attributed to a vascular accident occurring later in gestation, resulting in an ischemic insult to the developing bowel. Some studies have shown an association between jejunoileal atresias and defects that may cause strangulating obstruction of the intestinal tract (eg, malrotation, volvulus, intussusception, internal hernias, and gastroschisis). Cystic fibrosis (CF) may be found more often in newborns with jejunoileal atresia. Association with other congenital malformations is rare.

#### Diagnosis and Management

The prenatal diagnosis of intestinal atresia or stenosis is suggested by polyhydramnios. Duodenal obstruction is suggested by the findings of a dilated stomach and duodenum (double-bubble sign; Figure 108-9). Echogenic or dilated loops of bowel and abdominal cysts noted during fetal ultrasonography can indicate bowel obstruction. Despite improving prenatal ultrasound techniques, approximately two-thirds of newborns with intestinal atresias are diagnosed after birth.

The typical clinical presentation is a newborn infant with feeding intolerance, bilious emesis, abdominal distention (which is usually seen with distal small bowel obstruction/atresia rather than with proximal obstruction), and failure to pass meconium. If there is a suspicion of malrotation with or without volvulus, the patient should be considered to have a surgical emergency until proven otherwise. Neonatal and surgical consultation should be immediately obtained and the infant should be evaluated for transfer to a neonatal/pediatric intensive care unit for continuing care. A plain abdominal radiograph is the first step in evaluating such infants. The classic double-bubble sign

indicates duodenal atresia (Figure 108-10), whereas dilated loops of bowel with air-fluid levels indicate more distal obstruction such as jejunoileal obstruction (Figure 108-11). An upper-GI contrast study with small-bowel follow-through is useful to rule out malrotation or volvulus in cases with partial obstruction. Distal small-bowel obstructions are ruled out intraoperatively and a contrast enema is rarely required. Contrast enemas, when performed, may demonstrate microcolon and may help in ruling out rare colonic atresia or obstruction.

**Figure 108-9** Duodenal atresia. Note the double-bubble sign on the prenatal ultrasound. (Sonogram courtesy of Dr. Pe'er Dar, Montefiore Medical Center.)

**Figure 108-10** Duodenal atresia. Note the double-bubble sign with a large stomach bubble, smaller proximal duodenum, and no air in the distal bowel.

**Figure 108-11** Jejunal atresia. Note distended proximal bowel loops with no gas in the distal bowel.

A nasogastric tube should be placed to decompress the stomach and intestines, and fluid resuscitation and electrolyte management initiated. A blood gas may be obtained to check for evidence of metabolic or respiratory acidosis as this may provide information necessary for general management of these infants. In infants with duodenal atresia, a thorough evaluation for other congenital anomalies is important. In most infants, the workup can be completed after surgical repair with the exception of echocardiography to evaluate for congenital heart disease and, if considered urgent, abdominal ultrasound for evaluation of renal abnormalities. Genetic testing for Down syndrome in children with duodenal atresia should be obtained; workup for CF should be considered in infants with a diagnosis of jejunoileal atresia. Operative repair is most commonly performed with resection of the atretic segment and primary anastomosis. In some cases, temporary ostomy placement may be necessary, and in infants with multiple atresias, a staged approach may be required.

### Complications and Outcomes

The survival rate of patients with duodenal atresia is excellent (86%–90%) with early mortality (3%–5%) mostly related to coexisting congenital heart disease. Immediate postoperative complications include bowel obstruction, prolonged ileus, anastomotic leak, and wound infection. Late complications are reported to occur in 12% to 15% of patients, with an

associated 6% late mortality rate. Complications include megaduodenum with abnormal intestinal motility, blind loop syndrome, duodenogastric reflux and esophagitis, pancreatitis, cholecystitis, and cholelithiasis. Megaduodenum may present with poor weight gain, abdominal pain, and vomiting. It can be avoided or corrected with a tapering duodenoplasty. Blind loop syndrome occurs only in patients in whom a duodenojejunostomy was performed. GERD caused by dysmotility is common and may require either medical or surgical management. Patients with an annular pancreas have an increased tendency for late complications, often requiring a second operation. These patients should be monitored closely into adulthood as some of the complications (ie, peptic ulcer disease, gastric outlet and duodenal obstruction, pancreatitis, gastric cancer) manifest later in life.

Mortality rates for infants with jejunoileal atresia have decreased significantly, with survival approaching 100%. However, this does not include possible mortality related to short-bowel-syndrome (SBS) which is the most common and significant complication for patients with jejunoileal atresias. In most instances, infants are on total parenteral nutrition (TPN) for a short period of time only. In those who required more significant bowel resection and therefore greater loss of absorptive area, prolonged TPN dependence poses an additional risk for morbidity and mortality, including central line complications, sepsis, and TPN-related liver disease.

## MALROTATION AND MIDGUT VOLVULUS

In newborns who present with bilious vomiting, one of the most important diagnoses to exclude is malrotation with or without volvulus. Infants with volvulus constitute a surgical emergency and require prompt medical and surgical intervention. Up to 80% of affected patients are diagnosed during the neonatal period, with 50% presenting in the first week of life. If not recognized in a timely fashion, volvulus can lead to catastrophic loss of bowel with resultant lifelong disability, and even death.

### Embryology and Genetics

Normally, during fetal development the intestinal loop rotates counterclockwise around the superior mesenteric artery (SMA) and after returning into the abdominal cavity becomes firmly attached to the posterior abdominal wall, with the cecum positioned in the right lower quadrant and the duodenojejunal junction in the left upper quadrant. Malrotation results when the normal staged process of elongation, herniation with subsequent return to the abdomen, and finally fixation of the intestinal loop does not occur. Malrotation predisposes the infant to volvulus with strangulation of the intestines around the axis of the SMA; however, not all patients with malrotation experience this potentially life-threatening complication. There is a predominance of male patients who present during the newborn period; this gender

predilection is not observed in patients presenting after 1 year of age. Most children with malrotation do not have any predisposing syndrome or genetic susceptibility. Malrotation is often present in children with heterotaxia syndrome. Nonrotation is almost invariably present in children with CDH, omphalocele and gastroschisis. Other GI malformations that may be seen in patients with malrotation include atresias, Meckel diverticulum, intussusception, Hirschsprung disease (HD), GERD, gastric volvulus, persistent cloacae, and anomalies of the extrahepatic biliary system.

### Diagnosis and Management

With increasing accuracy of prenatal ultrasound, more cases of in utero volvulus or its sequelae are diagnosed antenatally; however, most infants are still identified after birth. The risk for midgut volvulus is highest in babies younger than 1 month. The most common presenting sign is bilious emesis, which should prompt an immediate evaluation for malrotation with or without volvulus. However, nonbilious emesis does not rule out malrotation and volvulus. Although bilious emesis is a general sign of intestinal obstruction, it can also be present in the absence of surgical pathology (up to 60%). The physical examination may be normal in up to 50% of the patients. Abdominal distention in the setting of malrotation and volvulus suggests the presence of ischemic bowel. There can be stooling abnormalities such as blood-stained (especially when strangulation of the intestines has occurred) and diarrheal stools. In cases where strangulation and necrosis of the bowel are advanced, the patient can present in shock, with abdominal distention and signs of peritonitis; these infants have a poor prognosis.

Plain abdominal radiographs in anterior-posterior and cross-table lateral position usually demonstrate a normal bowel gas pattern and are helpful in excluding other potential causes for bilious emesis such as intestinal obstruction/atresias. A normal bowel gas pattern on a plain radiograph, however, cannot exclude malrotation and volvulus. Signs of malrotation seen with an upper GI contrast study include incomplete obstruction of the duodenum, duodenojejunal flexure to the right of the expected location, proximal jejunal loops lying abnormally on the right side of the abdomen, and a high cecum seen with delayed follow-through films (Figure 108-12). Ultrasound with Doppler flow may be used to assess the position and relative relationship of the superior mesenteric vessels; reversal of the position of these vessels, the sonographic “whirlpool” sign, is highly sensitive for the diagnosis of midgut volvulus secondary to malrotation, but is not sufficiently accurate to exclude the diagnosis.

Management includes holding feeds, gastric decompression using a nasogastric or orogastric tube attached to continuous suction, and fluid resuscitation, as necessary. In addition to fluid resuscitation, prompt surgical intervention is indicated. The preferred surgical approach is the Ladd procedure, which consists of laparotomy with reduction of the midgut volvulus, if

**Figure 108-12** Upper gastrointestinal series in an infant with malrotation. Visualization of the position of the duodenum is key to assess for malrotation. The fourth portion of the duodenum should be seen to the left of the left spinal pedicle and should be near to the level of the pylorus. The main signs for malrotation are (1) abnormal position of the duodenojejunal junction, (2) spiral, “corkscrew,” or Z-shaped course of the distal duodenum and proximal jejunum, and (3) location of the proximal jejunum in the right abdomen.

present, in a *clockwise* fashion; division of peritoneal Ladd bands obstructing the duodenum; repositioning the bowel in a nonrotated state with the cecum in the left upper quadrant; and appendectomy. In select cases, the surgery can be done laparoscopically.

### Complications and Outcomes

The most commonly experienced complications are adhesions and the subsequent development of bowel obstruction. Neonates are particularly susceptible to this complication and parents should be counseled regarding this possibility. Recurrent volvulus, although rare, is an important complication. The overall survival for children with malrotation with volvulus is over 80%; however, a significant number of children experience substantial morbidity as a result of bowel loss with short-gut syndrome and its associated complications.

### GASTROSCHISIS AND OMPHALOCELE

Gastroschisis and omphalocele are the most common defects of the anterior abdominal wall. Gastroschisis presents as a full thickness defect in the abdominal

**Figure 108-13** A, Infant with gastroschisis. B, Plain chest and abdominal radiograph of an infant with gastroschisis.

wall with prolapse of the intestine through the defect (Figure 108-13). There is no covering membrane, and the defect lies to the right side of an intact umbilical cord. The incidence is 0.3 to 4 per 10,000 live births with increasing numbers for unknown reasons. In omphalocele, the defect is midline and the prolapsed organs are always covered with a protective membrane consisting of amnion on the outer surface, peritoneum on the inner surface, and Wharton's jelly in between (Figure 108-14). Omphaloceles contain a variable amount of intestine, often parts of the liver, and occasionally other organs. The umbilical vessels insert into the membrane and not the abdominal wall. The incidence is 1.5 to 3 per 10,000 live births, and unlike gastroschisis, the incidence has remained stable.

### Etiology and Genetics

Gastroschisis is considered to be the result of a vascular accident of the omphalomesenteric artery, a failure of mesoderm formation, rupture of the amnion around the umbilical ring with herniation of the midgut, or abnormal involution of the right umbilical vein with body wall weakening. Failure in the correct process of embryonic body wall folding is also hypothesized. There is no evident genetic cause seen in gastroschisis; however, young maternal age (<20 years old) has been strongly linked to it. Associated intestinal atresias occur in 6.9% to 28% of patients, most of them involving the GI tract, such as atresias and stenoses. These abnormalities are thought to be related to vascular compromise as well. In contrast, omphalocele is thought to be the result of herniation of the intestine and other abdominal organs into the umbilical cord without returning into the

abdominal cavity. It is associated with syndromes and chromosomal abnormalities in over 50% of cases, including Beckwith-Wiedemann syndrome (omphalocele, macroglossia, organomegaly, hypoglycemia and increased risk for childhood tumors such as Wilms tumor, neuroblastoma, and hepatoblastoma).

### Diagnosis and Management

Abdominal wall defects (AWD) are often detected during routine prenatal ultrasounds (Figure 108-14). The accuracy of the diagnosis may be affected by the timing of the fetal ultrasound, fetal positioning, or expertise of the ultrasonographer, therefore leading to undiagnosed and miscategorized defects. Both gastroschisis and omphalocele are associated with an increased risk of fetal growth restriction, premature delivery, and fetal death; therefore, careful obstetric follow-up with serial ultrasounds and other tests of fetal well-being are indicated. Maternal serum alpha-fetoprotein is usually elevated, with higher values in gastroschisis than omphalocele. Patients with AWD have a higher risk for intrauterine growth restriction, premature delivery, and fetal death. The expectant parents should be counseled by geneticists, pediatric surgeons, and neonatologists. It is important to prepare the parents for a prolonged neonatal intensive care unit stay as the newborn will need surgical intervention and is likely to have feeding intolerance, at least initially. Infants diagnosed prenatally should be delivered at a center where pediatric surgery is available immediately after birth. Although the timing of delivery of patients with gastroschisis is controversial, most infants can be delivered vaginally. There are no clear data supporting routine cesarean delivery, with the possible exception of giant omphaloceles.

**Figure 108-14** A, Prenatal ultrasound of an infant with a giant omphalocele. B, Plain chest and abdominal radiograph of an infant with omphalocele.

Regardless of the mode of delivery, the birth should be a coordinated event between the obstetricians and the neonatal and surgical providers. In the delivery room, a sterile field must be created on the infant warmer. Most physicians recommend the use of latex-free products in the care of these infants. In addition to the ABCs of newborn resuscitation, special care needs to be given to thermoregulation and management of the exposed bowel. The baby should be placed with the right side down in order to avoid kinking of the mesenteric pedicle, while the bowel is carefully stabilized and monitored for appearance. The exposed viscera and the lower half of the body are placed in a sterile transparent bowel bag, which is both easy and quick and allows for visualization of the defect and the exposed viscera. Alternatively, sterile gauze soaked in warm saline solution can be used to cover the defect, which is then carefully wrapped with sterile gauze around the body and eventually covered by either a sterile bowel bag or clear plastic wrap. Moist dressings alone without a covering plastic layer should be avoided as the newborn with gastroschisis has increased evaporative fluid and heat losses. When taking care of a patient with omphalocele, it is important to maintain the integrity of the sac. If the covering sac has ruptured, omphaloceles should be treated in a manner similar to gastroschisis.

Respiratory management can be difficult, especially if there is associated pulmonary hypoplasia or a significant cardiac lesion. Early intubation in the delivery room may be required as prolonged bag-mask ventilation or CPAP via mask should be avoided so as not to

distend the bowel. Irrespective of whether the infant requires respiratory support, a nasogastric tube should be inserted in order to prevent abdominal distention. Fluid and electrolyte management is challenging in patients with gastroschisis and ruptured omphaloceles since there are significant ongoing fluid losses that require volume resuscitation. Fluid requirements can range up to 2.5 times that of a healthy newborn. Initial resuscitation of these patients includes a 10 to 20 mL/kg bolus of normal saline or lactated Ringer solution in addition to maintenance IV fluids. Additional isotonic fluid should be administered, as needed, until urine output is established. Metabolic acidosis is common as a result of poor perfusion related to hypovolemia; therefore, acid-base balance should be monitored closely. Broad spectrum antibiotic coverage is also indicated in these patients.

For infants with gastroschisis, a common surgical approach is Silastic silo placement at the bedside which allows for covering of the defect and visual monitoring of bowel integrity. With appropriate fluid management and decompression of the intestines, the bowel wall edema decreases over time until the herniated intestine and other organs can be safely placed inside the abdominal cavity and closure of the abdominal defect can be attempted. A staged surgical approach may be necessary if the abdominal pressure is too high or in the presence of intestinal atresia.

If the sac of an omphalocele is intact, there is no urgency for surgical intervention. The infant can be stabilized and evaluated for associated anomalies. For smaller defects, primary closure with excision of membrane may

be possible. In the case of bigger defects, a common approach is topical application of sulfadiazine in order to allow for epithelialization of the membrane over weeks to months. Once associated problems have been addressed and enteral feeds established, the infant's care can be taught to the parents and continued on an outpatient basis. When the sac is sturdy enough to withstand external pressure, compression is done with elastic bandages while serially increasing the pressure until reduction of the abdominal contents is achieved and a ventral hernia repair can be performed, a process that may take 6 to 12 months.

### Complications and Outcomes

Outcomes for patients with gastroschisis depend mainly on the condition of the bowel at time of birth. Overall, the prognosis is excellent, with 90% to 95% survival rates. Mortality stems mainly from catastrophic bowel loss and sepsis. Infants often have prolonged hospitalizations (weeks to months), since feeding intolerance is a major problem, even with an otherwise intact bowel. GERD can be severe, and infants are at higher risk for developing necrotizing enterocolitis (in up to 20% of patients postoperatively). Long-term complications arise from short bowel syndrome, especially in infants who have associated intestinal atresia. However, even in infants with gastroschisis and intestinal atresia, most patients eventually do well after bowel rehabilitation and hyperalimentation. Outcomes for patients with omphalocele are greatly dependent on associated anomalies. Most of the mortality and morbidity is related to the associated anomalies rather than to the AWD itself. In isolated omphalocele without major cardiac defect and normal karyotype, survival rates between 75% and 95% have been reported. Pulmonary hypoplasia is a limiting factor to survival, especially in patients with giant omphalocele, who may have long-term ventilator dependency.

## ANORECTAL MALFORMATIONS (IMPERFORATE ANUS)

Anorectal malformations (ARM), a wide spectrum of diseases involving the distal anus, rectum, and the genitourinary tract, occur in 1 in 5,000 live births.

### Embryology and Genetics

Anorectal malformations are considered a complex malformation of the hindgut. Although the etiology remains unclear, it is likely to be multifactorial. Certain risk factors such as fever during pregnancy, being overweight, caffeine intake, cigarette smoking, and certain occupational exposures have been implicated in increasing the risk for ARM. There is a familial component to these malformations, with the risk for siblings approximately 1 in 100. Approximately 50% of patients have associated genitourinary malformations; additionally, ARMs are common in patients with syndromes such as VACTERL, trisomies, and OEIS (*omphalocele, exstrophy, imperforate anus, spinal defects*).

### Diagnosis and Management

ARMs are generally diagnosed in the nursery on the first physical examination when the patency and

correct position of the anal opening is assessed. Anal stenosis and anterior ectopic anus most likely represent imperforate anus with perineal fistula. If there is no opening or fistula visualized, there may be a low lesion with well-formed buttocks and a so-called "bucket handle" (midline skin bridge or thickened raphe). After 24 hours, a bluish or black discoloration in the area will likely indicate accumulation of meconium behind the lesion. In higher lesions, the buttocks and the perineal area may seem flat and there may be a prominent sacral dimple. Meconium passage may be noted through either the urethra (recto-urethral fistula is common in boys) or in the introitus anterior to the vaginal opening in female infants. Rectovaginal fistulas are exceedingly rare. In females, there may be a single perineal orifice consistent with cloaca. In addition, infants may present with delayed passage of meconium, emesis, and abdominal distention (which may be caused by accumulating meconium in the intestines, but may also be secondary to hydronephrosis or hydrocolpos).

The presence of other malformations should also be investigated. Tethered cord is present in approximately 25% of patients with anorectal malformations; a spinal ultrasound or MRI should therefore be obtained in all patients with this diagnosis. Abdominal sonography can be helpful, especially to evaluate the pelvic organs, kidneys, and bladder. Radiographs to exclude sacral anomalies and a voiding cystourethrogram should be performed.

Initial management includes gastric decompression and intravenous fluid management. For male infants, a piece of gauze should be placed around the penis in order to filter any meconium particles in the urine. It is important to observe the infant for 16 to 24 hours prior to initiating diagnostic testing since meconium and air take time to fill the rectal area. In the small percentage of patients for whom clinical evidence does not delineate the likely anorectal anomaly, a cross-table lateral abdominal radiograph with the patient in prone position, obtained after 16 to 24 hours, can help show the air column in the distal rectum (Figure 108-15).

If there is evidence for a recto-urinary tract communication, male infants should undergo fecal diversion with colostomy. Definitive repair in the newborn period can be attempted; however, the risks for an adverse outcome are high since the exact position of the rectum is not known and there is a risk of injury to the adjacent structures. A primary repair is performed in female infants with a perianal fistula only; a colostomy is generally performed for other defects. A diverting colostomy helps avoid infections and wound dehiscence. The definitive repair, posterior sagittal anorectoplasty (PSARP), is usually performed at approximately 1 year of age in both male and female infants. More recently, a laparoscopic approach has been used in selected cases.

### Complications and Outcomes

The mortality in patients with anorectal malformations is low and is mainly related to other associated anomalies or chromosomal abnormalities. Postoperative complications such as colostomy prolapse,

**Figure 108-15** Imperforate anus. Cross table lateral radiograph in prone position shows absence of bowel gas beyond the S2 vertebra. (Radiograph and MRI images courtesy of Terry Levin, MD, Department of Radiology, Montefiore Medical Center.)

stricture, and stoma complications have decreased significantly, especially since the introduction of PSARP. Constipation is the most common functional disorder after repair for ARM, especially in low lesions, and is generally thought to be related to impaired gut motility. Proactive management of constipation is important and includes the use of laxatives, dietary manipulations, and enemas. Overflow incontinence can be an issue for these patients as well. True fecal incontinence and soiling is present in a smaller group of patients and is more common in patients with high lesions and sacral abnormalities. In most cases, these children require a bowel management regimen to achieve socially acceptable fecal continence. Urinary incontinence is mostly associated with sacral and neurologic abnormalities such as tethered cord. Before the introduction of PSARP, urinary problems were more common particularly in high lesions. Females with ARM have a high incidence of genital malformations, the most common being vaginal and uterine septation anomalies and vaginal agenesis. Vaginal scarring can interfere with sexual intercourse and childbirth in adult life.

### MECONIUM ILEUS AND MECONIUM PLUG SYNDROME

Meconium ileus (MI) and meconium plug syndrome (MPS) are associated with delayed passage of stool in the newborn. Most full-term infants will pass stool by 24 hours (97%), and almost every baby will have done so by 36 hours (99.8%) of age. There is generally no difference in the time to the first stool between formula and breastfed infants. Premature infants often take longer to pass their first stool. MI represents obstruction of the small bowel caused by accumulation of sticky and inspissated intraluminal meconium. In most cases, this results from intestinal and pancreatic dysfunction associated with CF. However, it is important to note that not all patients with MI have CF. It is

the third most common cause of neonatal small bowel obstruction. The simple form involves obstruction only, whereas *complicated* MI includes associated conditions such as volvulus, intestinal atresia, necrosis, perforation, and meconium peritonitis. On the other hand, MPS represents a transient large bowel obstruction which is relieved by passage of meconium plugs. MPS can be considered a presenting symptom rather than a diagnosis in itself as up to 38% of infants with MPS will eventually be diagnosed with HD. Patients with CF may also present with MPS. There is also an overlap with small left colon syndrome (SLCS), commonly seen in infants of diabetic mothers.

### Etiology and Genetics

In most cases, MI is the earliest presenting symptom of CF, an autosomal-recessive disease that occurs in approximately 1 in 2,500 live white births. Whites are estimated to be heterozygous carriers at a ratio of 1:20. A fetus with CF produces abnormal meconium marked by stool hyperviscosity as well as changes in the meconium contents. These characteristics result in adherence of meconium to the mucosal surface of the small bowel leading to obstruction. If the impaction is progressive, it can lead to complicated MI. In contrast, there are no known genetic causes of MPS; however, there is an association with HD and SLCS. The etiology for MPS is largely unknown but suspected to be related to transient decrease in intestinal motility.

### Diagnosis and Management

Prenatal ultrasound may show polyhydramnios, echogenicity of the bowel, and intra-abdominal calcifications in cases with meconium peritonitis. Parents may have been screened for CF during pregnancy, and a carrier state should raise the index of suspicion for MI. *Simple* MI and MPS have overlapping clinical presentations with the common presenting signs being abdominal distention, delayed passage of meconium (>24 hours), and bilious emesis. Sometimes, the impacted meconium can be palpated. In cases with severe abdominal distention, especially in complicated MI, the newborn may experience respiratory distress and seem ill. A rectal examination is important to evaluate anal tone and the presence of meconium in the rectal vault. Rectal stimulation during the examination may trigger the passage of meconium plugs in the case of MPS. Abdominal radiographs in MPS show nonspecific intestinal dilatation. In patients with MI, plain abdominal radiography may show signs of either small- or large-bowel obstruction depending on the location of the obstruction (Figure 108-16 and Figure 108-17).

The infant should first be evaluated for general appearance and hydration status, and feeds held. If the infant seems to be in no acute distress, rectal stimulation should be performed to see if passage of meconium can be triggered. A glycerin suppository may be helpful in some cases. After passage of meconium plugs, the subsequent stooling pattern should be monitored carefully. As there is an association with HD and in some reports also with CF, workup for both these conditions should be considered. Suction rectal

**Figure 108-16** A, Meconium plug syndrome with small left colon syndrome. B, Contrast enema demonstrating meconium plug syndrome with small left colon.

biopsy to rule out HD should be performed in patients with MPS.

If abdominal distention is present, the intestines should be decompressed with an orogastric tube. In an ill-appearing infant, vascular access should be established and intravenous fluids started. Hyperosmolar gastrografin enemas are considered the initial diagnostic procedure, and are often therapeutic in patients with MPS. Gastrografin enemas evacuate meconium in approximately 40% of patients with MI and are associated with a lower mortality rate than surgery alone. In patients with MI, if passage of meconium cannot be achieved with an enema, enterotomy and irrigation are likely needed. Complications such as atresia, perforation, and meconium peritonitis require immediate surgical intervention, including intestinal resection and intestinal anastomosis/ileostomy. Meconium ileus is the earliest manifestation of CF in 10% to 20% of patients, therefore it is important to rule out the disease once the immediate condition has been treated. The infant should be evaluated by a geneticist and referred to a CF center for testing.

### Complications and Outcomes

Patients with MPS will develop a normal stooling pattern once the meconium plugs have been evacuated. However, it is important for parents to watch for constipation. Hirschsprung disease should be ruled out by suction rectal biopsy and CF genetic testing

with arrangements at the time of discharge for appropriate follow-up primary pediatric and subspecialty care. Simple meconium ileus often resolves with an enema alone, and therefore few complications occur. In some instances, initial feeding intolerance and abnormal peristalsis may be present but these usually resolve with time. If operative management is required, postoperative complications include wound infections, ostomy-related problems, need for parenteral nutrition, and short-gut syndrome. Patients with CF require lifelong supplementation with pancreatic enzymes, appropriate nutritional support for adequate intestinal function, and pulmonary management. The care for patients with CF has improved significantly over the last decades, and therefore the quality of life and overall life expectancy have improved.

### SMALL LEFT COLON SYNDROME

Small left colon syndrome is a functional disorder of the lower colon that produces signs of intestinal obstruction in the neonatal period. The condition is associated most commonly with maternal gestational diabetes mellitus. The magnitude of the problem is difficult to estimate because most of the literature is comprised of case series or case reports.

### Etiopathology

The exact etiology underlying small left colon remains unclear. Davis reported the presence of an increased

**Figure 108-17** Meconium ileus.

number of small immature ganglionic cells in the myenteric plexus and suggested this hypercellularity was similar to that found in the colon of premature infants. Philippart proposed that humoral and autonomic nervous system changes, occurring in response to neonatal hypoglycemia, may contribute to the development of decreased intestinal motility. Glucagon release and sympatho-adrenal stimulation are typical responses to hypoglycemia as well as stress. Both glucagon and sympathetic stimulation are known to decrease intestinal motility. This theory also explains the occurrence of small left colon in the absence of diabetes mellitus. Other possible contributors to intestinal hypomotility include maternal medications used during the third trimester. This concept is supported by the report of cases of neonatal SLCS in infants born to mothers using psychotropic drugs with known anticholinergic effects and the recognized association between hypermagnesemia (in infants born to mothers treated with magnesium sulfate) and hypomotility conditions.

### Diagnosis and Management

Most infants with small left colon are born at or near term and are of normal birth weight. Most of these infants have a history of maternal diabetes mellitus. There may also be a history of other maternal comorbidities (usually eclampsia) which contribute to neonatal stress or the use of psychotropic medications like lithium. Affected infants usually present with delayed passage of meconium (>24 hours of

**Figure 108-18** Small left colon syndrome. Contrast enema shows an abrupt transition in the caliber of the small colon with a large caliber rectum.

life), bilious emesis or nasogastric aspirates, and progressive abdominal distention that may rarely progress to intestinal perforation. Plain radiographs of the abdomen reveal distal intestinal obstruction with air fluid levels. If there is no evidence of intestinal perforation on the plain radiograph, a contrast enema should be performed. Findings on contrast enema include dilation of proximal colon with abundant intraluminal meconium, an abrupt cone-shaped caliber transition at or just distal to the splenic flexure, and a constricted descending and sigmoid colon with a larger caliber rectum devoid of meconium (Figure 108-18). However, the radiographic findings in this condition can seem similar to HD; therefore, a rectal biopsy is warranted to look for aganglionosis. If meconium ileus is suspected, screening for CF should be performed.

Management should be directed toward appropriate fluid resuscitation, decompression of the abdomen to relieve symptoms of intestinal obstruction, and antibiotics if clinically warranted. For most patients with SLCS, the contrast enema is not only diagnostic but also therapeutic. Most infants pass meconium spontaneously after the procedure. Enteral feeds should be initiated cautiously after meconium passage. Surgery is generally not required for most cases; surgical intervention is reserved for patients with intestinal perforation or those with refractory intestinal obstruction.

### Complications and Outcomes

Most infants with small left colon do not require surgical intervention and advance to full enteral feedings fairly rapidly. Reports in literature indicate normalization of intestinal caliber within a few weeks in

numerous patients who have undergone follow-up examinations of their colon. However, a small number of patients experience delayed complications such as recurrent or refractory obstruction or delayed perforation. This necessitates monitoring of these infants closely during the first few weeks of life.

### HIRSCHSPRUNG DISEASE

Also known as congenital aganglionic megacolon, HD has an overall incidence of 1 in 4,000 live births and accounts for 20% to 25% of cases of neonatal bowel obstruction. The disease is 4 times more common in boys than in girls.

#### Embryology and Genetics

The cause of HD is an absence of enteric neurons within the myenteric and submucosal plexus of the rectum or colon. Although the rectosigmoid is most often involved, a variable length of the intestine can be affected. Approximately 8% of patients with HD have Down syndrome.

#### Diagnosis and Management

Nearly all children with HD are diagnosed within the first 2 years of life, with approximately one-half of the children being diagnosed before 1 year of age. The mean age at diagnosis has decreased to 2.6 months, chiefly because of vigilance on the part of physicians and early use of rectal biopsy to confirm the clinical diagnosis. A common presentation in the newborn period is failure to pass meconium during the first 36 to 48 hours of life, abdominal distention, and vomiting. Although such infants subsequently pass meconium, their bowel movements are sparse and irregular. Older infants and children present with chronic constipation (but rarely experience soiling and overflow incontinence) and may be malnourished. Enterocolitis is thought to be caused by bacterial proliferation as a result of stasis and typically presents with abdominal pain, fever, foul-smelling or bloody diarrhea, and vomiting. If not recognized early, enterocolitis can progress to sepsis, transmural intestinal necrosis, and perforation, and can be fatal.

Rectal examination may result in explosive expulsion of stool when the finger is removed. Plain abdominal radiographs show gas and stool in the colon but absence of stool and gas distal to the pelvic rim (Figure 108-19). Contrast enema may reveal a transition zone that separates the small- to normal-diameter aganglionic bowel from the dilated bowel above. However, a transition zone may not be recognizable in up to 25% of neonates with classic HD, in patients with ultrashort-segment HD, and in patients with total colonic aganglionosis in whom the transition zone is above the colon. The presence of contrast in the 24-hour delayed abdominal film also suggests HD. The definitive diagnosis of HD is made by demonstrating the absence of ganglion cells in the rectal biopsy tissue. Additionally, acetylcholinesterase staining of the rectal tissue identifies hypertrophy of extrinsic nerve trunks.

Initial management includes intravenous hydration, withholding enteral feeds, gastric decompression, and

**Figure 108-19** Hirschsprung disease. Plain abdominal radiograph shows dilated bowel loops with paucity of air in the rectum.

serial rectal irrigations to decompress the bowel and prevent the development of enterocolitis. Patients with enterocolitis should be treated with decompression of the rectum with a large catheter and with warm saline irrigations several times a day, volume resuscitation, and administration of broad-spectrum antibiotics. In otherwise healthy newborns with short-segment HD and a normal-caliber colon, a single-stage ileoanal pull-through procedure may be performed. In patients with associated enterocolitis or a significantly dilated colon, surgical management includes a staged procedure with placement of a diverting colostomy at the level of normal bowel, and rectal irrigations followed by rectal resection with a pull-through procedure once the bowel caliber is restored to normal. The ability to perform a single-stage pull-through procedure largely depends on the availability, experience, and capabilities of the staff pathologist because aganglionic intestine must not be in the pull-through segment.

#### Complications and Outcomes

Postoperative complications include intermittent fecal soiling and incontinence, anastomotic leak, stricture formation, intestinal obstruction, and enterocolitis. Most children achieve fecal continence; however, children with Down syndrome may be expected to have lower rates of fecal continence. Management of postoperative enterocolitis includes rectal irrigations several times a day and antibiotic therapy; in some cases, application of topical nitric oxide, posterior

myotomy/myomectomy, or injection of botulinum toxin may be warranted.

### SUMMARY

It is important for pediatricians to have a high index of suspicion and be familiar with a stepwise approach to the evaluation of neonates with GI symptoms. A complete physical examination and assessment of the patient's overall clinical condition should be followed by appropriate radiographic studies and blood tests. In cases with congenital anomalies, further evaluation of associated anomalies or syndromes is important. Early subspecialty involvement can save valuable time and expedite patient care. Discussions with the family regarding the immediate delivery room management (in cases of antenatal diagnosis) as well as long-term management and anticipated complications can help ease parental anxiety and concerns.

Lastly, for the pediatrician caring for older children, it is important to remember that some of these patients can have long-term consequences that may, at first glance, seem not to be directly related to the original disease.

## SECTION FOUR

# Perinatal Care: Caring for the High-Risk Infant

### Chapter 109

## ASSESSMENT AND STABILIZATION AT DELIVERY

Joaquim M. B. Pinheiro, MD, MPH

Most neonates successfully meet the challenge presented by labor, the delivery process, and subsequent adaptation to the extrauterine environment. Birth is the riskiest stage of life because failure of postnatal transition can result in immediate physiologic instability, end-organ dysfunction, and disability or death. Approximately 10% of neonates require some resuscitative assistance during transition in the delivery room. In subgroups such as very low-birth-weight newborns, (<1,500 g), 90% require immediate respiratory support; although most of these neonates need only oxygen, approximately 6% receive advanced resuscitation, including chest compressions.

Prenatal history and intrapartum evaluation allow physicians to anticipate most newborns who will need resuscitation after delivery; still, unexpected complications are common. Immediate assistance aimed at ensuring stabilization and appropriate transition of the neonate must be available and effectively implemented, usually in the first few minutes of life. Thus, the American Academy of Pediatrics (AAP) and American College of Obstetrics and Gynecology (ACOG), in their *Guidelines for Perinatal Care*, recommend that “[a]t every delivery, there should be at least one individual whose primary responsibility is the newborn and who is capable of initiating resuscitation, including positive pressure ventilation (PPV) and chest compressions. . . . Either this individual or someone else who is immediately available should have the skills required to perform a complete resuscitation, including endotracheal intubation, establishment of vascular access, and the use of medications.”

A skilled resuscitator does not suffice to ensure an effective resuscitation. An integrated approach involving all perinatal staff is needed for immediate recognition of distressed neonates, communication among care providers, and rapid implementation of accepted resuscitation procedures. The Neonatal Resuscitation Program (NRP), jointly sponsored by the American Heart Association and the AAP, provides evidence-based guidelines and expert opinion on neonatal resuscitation. The guidelines include a curriculum for training and evaluating neonatal primary care physicians, individually and in teams, and practical tools to guide resuscitation. Because the NRP curriculum is now used to train most providers of neonatal resuscitation in the United

States and in many other countries, hospitals base their neonatal resuscitation procedures on principles espoused by the NRP, adapted to local resources. As a result, this chapter suggests practices generally aligned with those published by the NRP. Of particular note are NRP recommendations including delayed cord clamping in selected neonates, de-emphasis of color in favor of pulse oximetry to assess oxygenation, restriction of oxygen use during postnatal transition, and less aggressive suctioning of the airway in both meconium-stained and other newborns.

This chapter is intended for primary care physicians and other providers of neonatal primary care who may practice at hospitals without a tertiary care perinatal center. It focuses on practical evaluation and management of neonates who need assistance during transition in the delivery room setting. After briefly reviewing the physiologic basis of neonatal resuscitation, it outlines the necessary physical infrastructure, provider roles, and procedures for routine and contingency resuscitations. Routine care of neonates and evaluation of sick newborns after the delivery room transition are addressed in Chapter 110, Identifying the Newborn Who Requires Specialized Care; and Chapter 114, Follow-up Care of the Graduate From Neonatal Intensive Care.

### ANTICIPATING HIGH-RISK DELIVERIES

Prenatal anticipation of the need for neonatal resuscitation allows time for adequate preparation. Significant resuscitative interventions in the delivery room can be expected in very premature newborns (with gestational age <32 weeks [32%–32%]) and those with major congenital malformations.

Gestational age should be assessed before birth because obstetric criteria are more accurate for this purpose than a postnatal physical examination that uses a method such as the New Ballard Score. An accurate approximation of gestational age is particularly crucial in deliveries around the edge of viability, between 21 and 25 weeks of gestation. Because no official algorithm exists to ensure uniform determinations of gestational age by obstetricians, finding discrepant gestational ages on a maternal record is common. Primary care physicians should verify the obstetric estimation of gestational age, which is optimally based on the first day of the mother's last menstrual period, and confirmed by an early prenatal ultrasound. Proper advanced planning, which ranges from withholding resuscitation to advanced notification of a regional center's transport team, is contingent on obtaining reliable gestational age estimates.

**BOX 109-1 Factors That Increase the Likelihood of Neonatal Resuscitation****PREPARTUM PRESENTATION**

- Indicated preterm delivery<sup>a</sup>
- Magnesium sulfate<sup>a</sup>
- Maternal infection<sup>a</sup>
- Oligohydramnios<sup>a</sup>
- Hydrops fetalis<sup>a</sup>
- Major fetal malformations<sup>a</sup>
- Multiple gestation<sup>a</sup>
- Size-date discrepancy<sup>a</sup>
- Lung immaturity
- Premature rupture of membranes
- Postterm gestation (>42 weeks' gestation)
- Diminished fetal activity
- Polyhydramnios
- Fetal anemia
- Maternal hypertension
- Maternal diabetes
- Maternal drug abuse
- Acute maternal illnesses
- Recent vaginal bleeding
- Maternal adrenergic blockade
- No prenatal care

**INTRAPARTUM PRESENTATION**

- Preterm delivery<sup>a</sup>
- Chorioamnionitis<sup>a</sup>
- Meconium-stained amniotic fluid<sup>a</sup>
- Abnormal fetal heart rate<sup>a</sup>
- Emergency cesarean delivery<sup>a</sup>

- Placental abruption<sup>a</sup>
- Cord prolapse<sup>a</sup>
- Maternal narcotics <4 hours before delivery
- Abnormal presentation (breech, transverse)
- Placenta previa
- Cord compression
- Precipitous labor
- Prolonged labor
- Prolonged second stage of labor >2 hours
- Shoulder dystocia
- Uterine tetany
- Ruptured membranes >18 hours
- General anesthesia
- Maternal hypotension
- Forceps- or vacuum-aided delivery

**POSTPARTUM PRESENTATION**

- Severe respiratory distress<sup>a</sup>
- Drug-induced depression<sup>a</sup>
- Central nervous system injury<sup>a</sup>
- Central nervous system anomalies
- Spinal cord injury
- Airway obstruction
- Sepsis or infection
- Diaphragmatic hernia
- Pneumothorax
- Deformities
- Abdominal anomalies

<sup>a</sup>Most common and significant conditions.

Congenital malformations identified prenatally, whether necessitating neonatal surgery or potentially interfering with cardiorespiratory transition at birth, may require specialized resuscitative interventions in the delivery room.

Common intrapartum exposures such as maternal magnesium sulfate therapy and chorioamnionitis are usually identified well in advance of the delivery. However, meconium staining of the amniotic fluid and significant decelerations of the fetal heart rate are most often noted just before delivery. Review of the obstetric history is useful to identify these and other factors (Box 109-1) that may affect the newborn's need for resuscitation and early postnatal care.

A continuum of risks is anticipated at delivery. Each institution should establish specific criteria delineating which deliveries require the presence of a separate team to care for the neonate, as well as the composition of such a team, according to level of risk. The traditional practice of calling a neonatal team to every cesarean delivery, initially justified by the use of general anesthesia in the mother and the frequent presence of fetal distress as the indication for urgent surgical delivery, is no longer sensible. Rates of cesarean section delivery now exceed 30% in the United States, with many

medically and socially elective surgical deliveries, prompted by prior cesarean deliveries or maternal choice. Given that the need for pediatric staff attendance at low-risk, elective cesarean deliveries is controversial, individual hospital obstetric and newborn service providers should consult with their risk management department to develop policies and programs that best serve their unique circumstances.

## ESSENTIAL TRANSITIONAL CARDIORESPIRATORY PHYSIOLOGY

The successful establishment of cardiorespiratory function in the newborn requires adequately grown and unobstructed conducting airways, gas-exchanging airways with sufficient surfactant and matching pulmonary vasculature, removal of fetal lung fluid, sustained breathing, and a rapid increase in pulmonary blood flow. These changes result in a gradual rise in preductal O<sub>2</sub> saturation (SpO<sub>2</sub>) from 65% to 90% over the first 10 postnatal minutes (Figure 109-1). Anatomic or functional derangements in 1 or more of these areas can result in cardiorespiratory insufficiency in the newborn. Although these functions may be approached by following the ABC (airway, breathing, circulation)

**Figure 109-1** Targeted preductal SpO<sub>2</sub> in the 10 minutes following birth, reflecting the ranges expected in normal neonates. Note the gradual rise in SpO<sub>2</sub> from 65% to 85%–95%. (Drawn from data in Kattwinkel J, Perlman JM, Aziz K, et al. Neonatal Resuscitation: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Pediatrics. 2010;126:e1400–e1413.)

sequence commonly taught for resuscitation, each requires integration of respiratory, hemodynamic, neurologic, and other inputs.

A functional airway must be anatomically normal, externally straight and uncompressed, and unobstructed by intrinsic structures such as the tongue or vocal cords; its lumen must also be clear of extraneous matter (eg, amniotic fluid, meconium, blood, secretions). The initial postnatal breaths clear lung fluid from the airways and establish a gaseous functional respiratory capacity; normal tone of pharyngeal and laryngeal muscles sustains a patent upper airway. Thus, any condition that causes apnea, generalized hypotonia, or laryngospasm at birth will compromise the airway.

Box 109-2 lists common or typical causes of symptomatic airway obstruction in the immediate postnatal period. They are categorized according to whether they are extrinsic to the airway, intrinsic to airway structures, or the result of removable luminal fluids or particulates. The actual incidence of these conditions is unknown, and they may coexist (eg, mild laryngomalacia, nasal secretions, nasal mucosal edema). Iatrogenic causes are emphasized because they are common and mostly preventable. For example, airway obstruction can easily occur during bag-mask ventilation, through mandibular pressure from the mask or from impingement of the resuscitator's fourth and fifth fingers on submandibular tissue. Laryngospasm can be readily induced by mechanical stimulation of the hypopharynx or larynx with a suction catheter or laryngoscope.

In the newborn, initial breaths inflate and aerate the lungs and promote gas exchange. Each of these elements has independent and synergistic physiologic effects. Lung inflation decreases vagal tone, directly diminishing the apneic and bradycardic effects of vagal activity. Lung inflation and aeration each

### BOX 109-2 Common or Prototypical Causes of Airway Obstruction in the Newborn

#### EXTRINSIC

- Mandibular pressure from facemask<sup>a</sup>
- Submandibular pressure from resuscitator's fingers<sup>a</sup>
- Kinked upper airway (flexed or hyperextended)<sup>a</sup>
- Masses (eg, epulis)
- Vascular ring

#### INTRINSIC (PARIETAL)

- Hypotonic pharyngeal muscles, tongue
- Laryngospasm
- Nasal trauma, edema
- Airway malformations (Pierre Robin sequence, choanal atresia)
- Laryngomalacia
- Vocal cord paralysis

#### INTRALUMINAL

- Pharyngeal secretions (with or without meconium, blood)
- Nasal secretions
- Residual lung fluid
- Aspiration of upper airway fluid and suspended particles

<sup>a</sup>Most common and significant conditions.

decrease pulmonary vascular resistance, allowing the postnatal increase in pulmonary blood flow necessary for gas exchange; the latter is optimized by the inflation-induced stimulation of surfactant secretion. The subsequent increase in systemic oxygenation has additional vagolytic effects.

Significant intrapartum hypoxia and exposure to common medications such as magnesium sulfate and narcotics depress respiratory drive, producing hypopnea or apnea in the newly born. Common and archetypal causes of apnea in the delivery room are listed in Box 109-3. In most instances, the neonate exhibits primary apnea, which is induced by respiratory reflexes and is thus readily reversed. Secondary apnea is much less common because it reflects significant hypoxia-ischemia, with resulting metabolic dysfunction of the central respiratory apparatus. Protracted depression of the respiratory drive can also be the result of transplacental transfer of maternal medications with neuroinhibitory effect.

Hypoventilation may occur despite unobstructed conducting airways and normal or increased respiratory effort. Common or typical conditions causing hyperpneic respiratory failure include severe lung immaturity (respiratory distress syndrome), lung hypoplasia (diaphragmatic hernia, oligohydramnios), and external impediments to lung inflation (tension pneumothorax, large pleural effusions, thoracic hypoplasia).

### BOX 109-3 Common or Prototypical Causes of Apnea or Hypopnea in the Newborn

- Hypoxemia
- Reflexes elicited by trigeminal or ocular pressure, laryngeal stimulation
- Deflated lungs
- Airway obstruction
- Magnesium sulfate
- Recent intrapartum narcotics
- General anesthesia (rare)
- Hypoxia-ischemia

Circulatory adequacy depends on heart rate and stroke volume. Thus, cardiac output is compromised by bradycardia, acute hypovolemia, or both. In addition, an inadequate increase in pulmonary blood flow at birth will cause functional circulatory insufficiency with consequent hypoxemia. Rare anatomic defects such as transposition of the great vessels with intact ventricular septum can produce severe, persistent hypoxemia from birth. However, cardiovascular lesions that depend on patency of the ductus arteriosus for maintenance of pulmonary or systemic blood flow would not become symptomatic in the delivery room.

Common causes and clinical correlates of inadequate transition from fetal to newborn circulation are listed in Box 109-4. Acute hypovolemia is particularly difficult to diagnose because pallor and peripheral vasoconstriction commonly result from the catecholamine surge induced by fetal or neonatal distress (or both) and acidosis. However, when these symptoms occur in the setting of a tight nuchal cord, hypovolemia caused by significant fetoplacental transfusion should be suspected; this condition is likely underdiagnosed and occurs in approximately 3% of deliveries at term. Clamping of the umbilical cord early after birth interrupts the normal return of placental blood to the newborn, resulting in a blood volume deficit in excess of 20 mL/kg birth weight, which may be prevented by delaying cord clamping for 30 to 60 seconds (see section on delayed umbilical cord clamping).

Another typical transitional disorder is persistent pulmonary hypertension, with right-to-left shunt at the level of the foramen ovale and ductus arteriosus and with consequent systemic hypoxemia. The persistently increased pulmonary vascular resistance may result from a combination of inadequate lung inflation, alveolar hypoxia, hypoventilation, and acidosis; these complications may be superimposed on hypoplastic or hyperreactive pulmonary vasculature, and they may be exacerbated by hypothermia developing during resuscitation.

Thermoregulation is a fundamental but easily overlooked aspect of transition in neonates requiring cardiopulmonary resuscitation. Hypothermia can develop within minutes, and it adversely affects circulatory transition because it induces pulmonary vasoconstriction and increases oxygen consumption. Thus, efforts

### BOX 109-4 Common or Prototypical Causes of Inadequate Circulatory Transition in the Newborn

- Acute hypovolemia (nuchal cord, fetoplacental or fetomaternal transfusion, placental abruption, cord accidents, early cord clamping)
- Prolonged fetal bradycardia
- Persistent pulmonary hypertension (lung hypoplasia, fetal distress, meconium aspiration, asphyxia)
- Hypothermia
- Polycythemia
- Hydrops fetalis
- Transposition of the great vessels (with intact ventricular septum)
- Cardiomyopathy
- Pneumopericardium
- Tension pneumothorax

to maintain a neutral thermal environment and minimize heat losses should precede resuscitation and be sustained while performing other interventions (in mnemonic terms, T-ABC[D] [temperature, airway, breathing, circulation, drugs]).

## ACUTE FETAL HYPOXIA AND ASPHYXIA

Despite the myriad causes of cardiorespiratory insufficiency in the neonate, acute hypoxia that develops during or immediately after birth is a central feature of most transitional disorders. Sustained hypoxemia and ischemia result in asphyxia and ultimately death. Intermittent fetal hypoxia occurs normally with uterine contractions as a result of decreased uterine blood flow, umbilical cord compression, or both. Pathologic intrapartum hypoxia likely develops most often in susceptible human fetuses by repetitive cord compression and incomplete recovery between contractions.

Much of the understanding of the physiology of asphyxia is extrapolated from Dawes' experiments with acute total asphyxia in a normal newborn rhesus monkey model. Figure 109-2 illustrates the progression of cardiorespiratory and neurologic dysfunction during acute asphyxia, produced by delivering the animal's head into a saline-filled bag and clamping the umbilical cord. The initial response to hypoxia is reflex (primary) apnea and bradycardia. Progressive mixed acidosis ensues and induces gasping, which ceases as the respiratory centers develop severe metabolic dysfunction; this stage is the phase of secondary (or terminal) apnea and bradycardia, during which neurologic responsiveness has been lost, and only artificial resuscitation can avert death. Permanent brain injury may develop during this stage. Resuscitation with PPV results in immediate recovery of the heart

**Figure 109-2** Sequence of cardiorespiratory and neurologic abnormalities during total acute asphyxia followed by positive pressure ventilation in newborn rhesus monkeys. (From Dawes GS. Fetal and Neonatal Physiology. Chicago, IL: Year Book Medical Publishers, Inc; 1968:149. Copyright 2008 Elsevier Ltd. Reprinted by permission.)

rate, return of blood pressure, and finally, the reappearance of gasping respirations.

The importance of reflex mechanisms in determining immediate cardiorespiratory responses in the newborn cannot be overemphasized. Natural and iatrogenic stimuli, including hypoxia, acidosis, lung deflation, trigeminal pressure, and secretions or mechanical irritation in the periglottic region act synergistically to induce laryngeal closure, central apnea, and bradycardia. These reflex responses are mediated through arterial chemoreceptors and vagal and somatosensory afferents. Conversely, simple lung inflation stimulates pulmonary stretch receptors, producing an immediate vagolytic effect while desensitizing laryngeal and carotid body reflexes and inducing further deep inspirations through the Head paradoxical reflex. Adequate lung inflation, whether spontaneous or assisted, is therefore paramount in restoring spontaneous cardiorespiratory and neurologic function in the depressed newborn.

**Figure 109-3** Recovery of clinical signs within the Apgar scoring system in response to assisted ventilation. Immediate responses are reflexive in nature; the cycle is sustained by oxygen transport and metabolism.

Cardiorespiratory depression in a newborn thus results from cardiorespiratory reflexes superimposed on and interacting with a continuum of hypoxia-ischemia. Rapid assessment of the severity of physiologic dysfunction in the individual baby is essential to apply appropriate resuscitative measures. In the clinical setting, practical evaluation methods must be used in place of invasive physiologic measurements. The Apgar scores were traditionally devised for this purpose, but they are no longer recommended as a guide to resuscitation, partly because evaluation of heart rate, respirations, tone, reflex irritability, and color cannot be done rapidly, reliably, and unobtrusively in emergency conditions. The NRP now recommends repeated assessment of the dyad of respirations and heart rate to guide further interventions in the delivery room, whereas pulse oximetry should replace color when evaluating SpO<sub>2</sub>. Nevertheless, Apgar scores are still routinely obtained to assess the condition of the newborn. Both the Apgar scoring system and the abbreviated NRP evaluation method can be fundamentally understood from the continuum of perinatal depression studied by Geoffrey Dawes in animal models and observed by Virginia Apgar in human newborns.

As shown in Figure 109-3, the 5 clinical signs in the Apgar scoring system can be considered as sequential steps in a cycle of oxygen transport and utilization. Individual signs are further linked through reflex mechanisms. Conditions that depress fetal cardiorespiratory or neurologic function in the immediate perinatal period will produce primary apnea and hypoventilation in the newly born. Failure of lung inflation, aeration, and oxygenation triggers a sequence of progressive dysfunction. The increased vagal tone causes reflex (*primary*) apnea and bradycardia. Consequent progressive hypoxia produces cyanosis and promotes gradual loss of neuromuscular function. Sustained hypoxia results in metabolic dysfunction in the muscular and central neurologic systems, culminating in secondary apnea and

concurrent unresponsiveness to stimuli. Asystole follows prolonged, severe hypoxia.

Figure 109-3 depicts the sequence of recovery of functions when effective resuscitation with positive pressure ventilation is applied before the onset of asystole. The vagolytic effect of lung inflation immediately increases heart rate. Peripheral oxygenation then visibly improves, and neuromuscular function gradually recovers, ultimately producing sustained respirations.

Understanding these intrinsic relationships within the Apgar system facilitates the assessment of depressed newborns independently of the attribution of numerical scores. The abbreviated evaluation scheme suggested by the NRP includes initial muscle tone followed by repeated rapid assessment of respirations and heart rate, then oxygenation through oximetry. The NRP method effectively uses the same basic functions as the Apgar system without the obtrusive scoring. Given the interdependence of the 5 clinical signs, isolated abnormalities in any measure should suggest specific causes directly affecting that sign and unrelated to hypoxia (eg, sustained bradycardia in a pink, vigorous newborn might indicate congenital heart block).

The concerns about hypoxia must be complemented by the understanding that even brief hyperoxia during or following resuscitation may exacerbate adverse neonatal outcomes.

## RESUSCITATION IN THE DELIVERY ROOM

### Withholding, Limiting, or Withdrawing Resuscitation

Resuscitation of the newborn is a medical intervention with variable effectiveness, benefits, and risks, which largely depend on the baby's underlying conditions and gestational age. In keeping with ethical principles, resuscitation should not be applied indiscriminately to all newborns with cardiorespiratory depression, particularly when the prognosis for survival is poor or when survival will likely be burdensome to the child. Because most delivery room resuscitations are expected, time is usually available to discuss the expected outcomes with the family. An evidence-based, family-centered valuation of the outcomes of resuscitation should guide clinical decision making in the delivery room. Ideally, the obstetric and pediatric physicians and the parents would reach a common understanding of the goals of resuscitation before the time of birth. Only then can the extent of interventions be tailored to the individual mother and baby—including the options of continuous fetal monitoring, cesarean delivery, and withholding or limiting resuscitation of the newborn.

Resuscitation and subsequent intensive care are indicated when survival is likely and risk for unacceptably severe morbidity is low.

Resuscitation is generally not indicated in babies with poor prognoses that entail early death or major morbidities in the rare long-term survivor. Newborns in this category may include those of confirmed gestational age less than 23 weeks or birth weight below 400 g, those with anencephaly, and

those with confirmed trisomy 13 or 18 or other known lethal anomaly. Comfort care and support of the family are always indicated.

Noninitiation of resuscitation is also appropriate at the parents' request for some infants with uncertain prognosis, including those with high probability of death or extreme morbidity. Newborns at 23 to 24 weeks' gestation typify a situation in which the parents' wishes for resuscitation should be ascertained, respected, and supported by physicians. To provide accurate information to parents, physicians must first attempt to minimize the uncertainty inherent in gestational age determinations, and consider additional prognostic factors such as gender, weight, antenatal glucocorticoid exposure, and multiple gestation. A calculator of expected outcomes in extremely preterm births is available online at [www.nichd.nih.gov/about/org/der/branches/ppb/programs/epbo/Pages/epbo\\_case.aspx](http://www.nichd.nih.gov/about/org/der/branches/ppb/programs/epbo/Pages/epbo_case.aspx). This approach is suggested by the NRP and supported by the AAP Committee on Fetus and Newborn and the Canadian Paediatric Society.

### Preparing for Resuscitation

To maximize the efficiency of stabilization during the initial, crucial 10 minutes after birth, the resuscitation team should be organized in advance, familiar with the available equipment, and informed about the prenatal factors relevant to accurate assessment of the individual newborn (Box 109-5).

Before or at arrival at the delivery site, the resuscitation team can rapidly assess the fetal condition by ascertaining gestational age, other major underlying diagnoses, and evidence of fetal distress. Next, the resuscitation equipment and medications can be checked and organized systematically by applying the T-ABC(D) mnemonic. Team leadership and additional roles should be defined, and additional support should be sought if needed. If time permits, a more detailed assessment of the fetal and maternal risk factors can then be undertaken. The pediatric team should assess and plan the resuscitation by communicating clearly with the obstetric staff and the family, among themselves, and with a tertiary care center if neonatal transport is anticipated.

By directly observing the last few minutes of the delivery, rather than waiting by the resuscitation table, the team leader can obtain useful information that is often not verbally communicated. This information may include the fetal heart rate pattern during the last contractions, presence or absence of meconium or blood in the mouth, a tight nuchal cord, the baby's facial response to suctioning or handling, and the tone immediately after expulsion. Awareness of these factors allows the resuscitator to stay a step ahead and quickly identify the hypovolemic baby after a fetoplacental transfusion or question the reported absence of heart rate in the newborn who had some flexor tone after expulsion, 40 seconds prior.

## INITIAL POSTNATAL EVALUATION AND INTERVENTION

The general flow of neonatal resuscitation, according to the NRP, is shown in Figure 109-4.

**BOX 109-5 Domains of Preparation for Delivery Room Resuscitation****ASSESSMENT OF THE FETUS**

- Gestational age
- Anticipated fetal pathologic abnormality
- Signs of fetal distress
- Fetal heart rate tracing
- Meconium
- Pregnancy history
- Course of labor
- Intrapartum medications
- Risk factors for infection
- Other (eg, major bleeding)

**RESUSCITATION EQUIPMENT****Thermoregulation**

- Warmer, towels, plastic wrap

**Airway**

- Suction (bulb syringe and wall), catheters, meconium aspirator

- Intubation equipment (functioning laryngoscope; endotracheal tubes)

- Laryngeal mask airway

**Breathing**

- Ventilation equipment, tubing, blended oxygen supply and pulse oximeter, carbon dioxide detector

**Circulation**

- Location of medications, catheters

**Drugs**

- Other medications, if needed (eg, surfactant)

**PERSONNEL ROLES**

- Airway manager
- Assistant to monitor heart rate
- Other assistants as needed

Cycles of assessment and consequent appropriate intervention are repeated at approximately 30-second intervals, following the ABC(D) sequence, while thermoregulation is maintained throughout. Subsequent care, from routine to postresuscitation stabilization, depends on the level of intervention needed during the initial resuscitation. This algorithm may be used to perform a quick initial assessment of a newborn. Three essential questions are asked, as listed in Box 109-6. The first question can be answered before delivery, and the last 2 within seconds after birth. For most newborns, the answer to these 3 questions is yes, and such newborns require only thermoregulatory support (warmth and drying), maintenance of an open and clear airway, and assessment of color to verify respiratory and circulatory efficacy. Such babies can remain with their mothers. The subsequent discussion applies to the few newborns who need assistance with transition.

Very premature newborns ( $\leq 28$  weeks' gestation) lose heat rapidly, and they often develop hypothermia despite standard thermoregulatory care. The delivery or resuscitation room temperature should be increased to 77°F to 79°F (25°C–26°C), if possible. Prewarmed, dry blankets diminish conductive heat losses. Most important, convective losses should be minimized by immediately covering the baby with a plastic barrier. This goal can be achieved by placing the baby in a clean, food-grade polyethylene bag. Alternatively, 2 sheets of nonadhesive Saran-type wrap (or another brand of polyvinylidene chloride film) can be used to wrap the head and the body below the neck, respectively. In some settings, using exothermic mattresses and a warmed incubator for transfer to the neonatal unit may also be helpful.

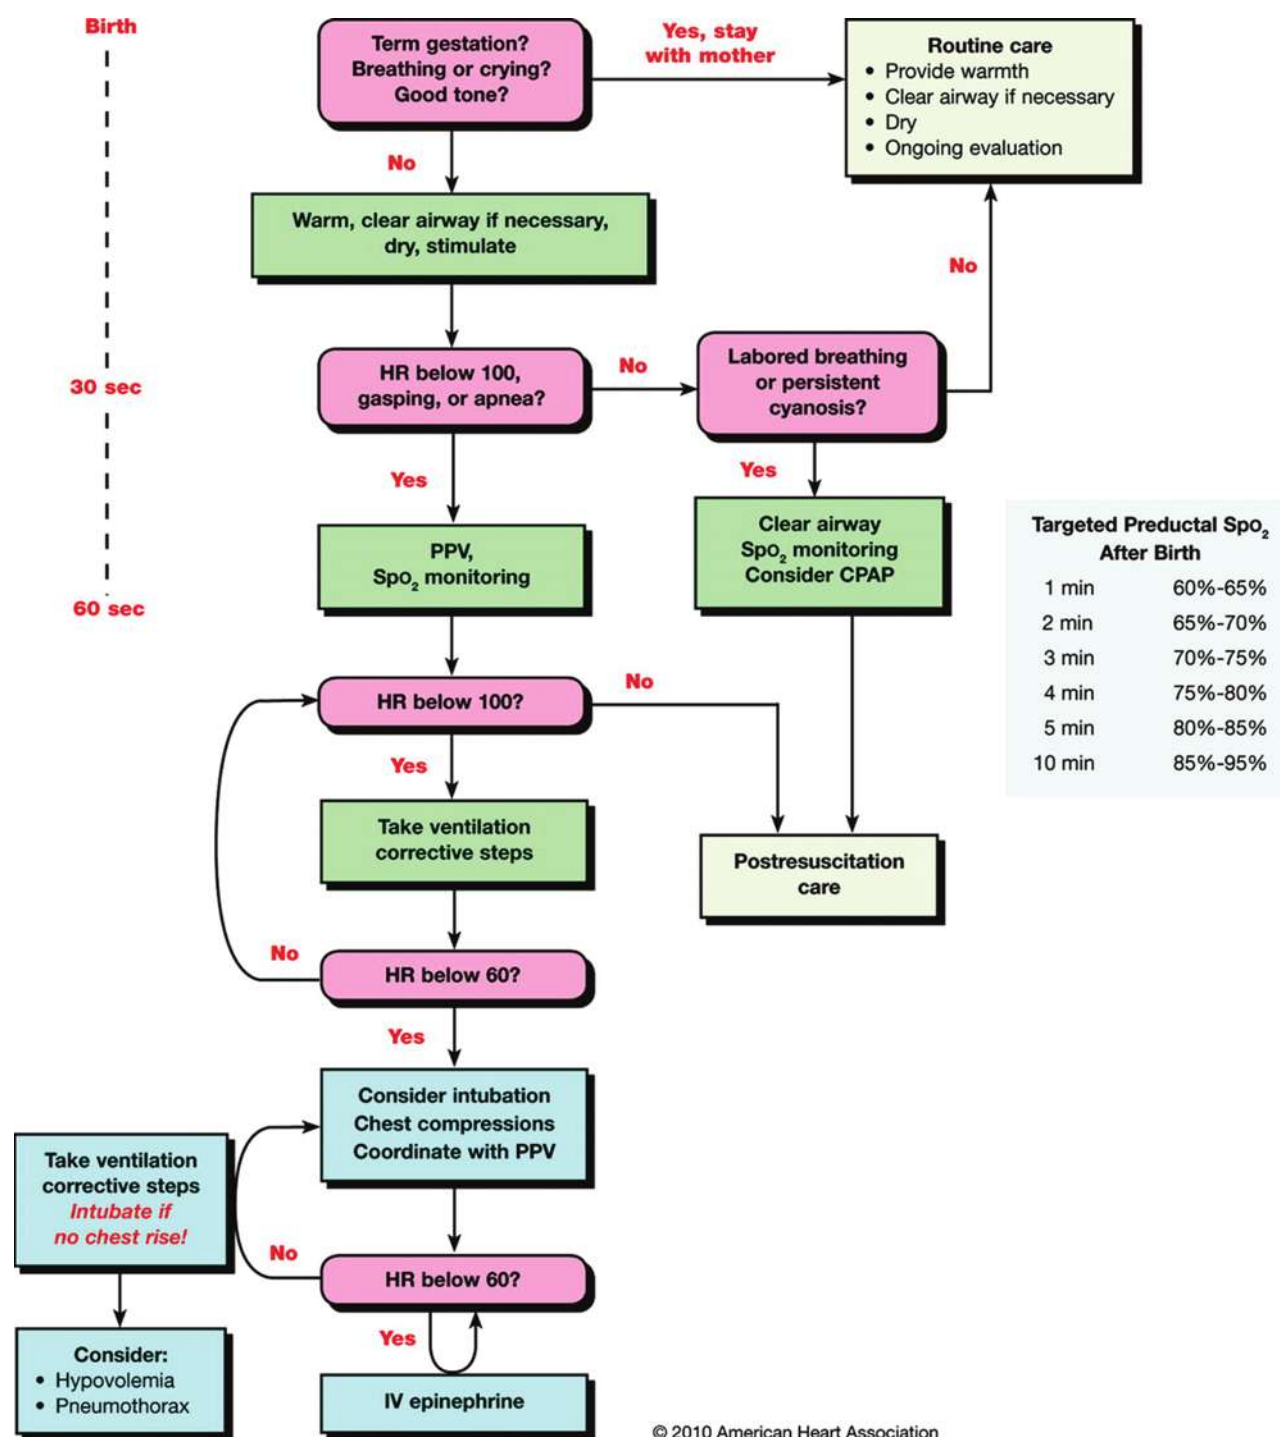

If the amniotic fluid contains meconium, blood, or infected matter, or if the newborn infant is not breathing

or exhibits hypotonia, then immediate airway management is needed while supporting thermoregulation.

The airway can be approached by external positioning and internal suctioning, in that order (see Box 109-2). External patency is ensured by positioning the head so that the neck is slightly extended, in the sniffing posture; the mandible should be lifted anteriorly. Internal airway patency is achieved by suctioning to remove obstructing matter (meconium, bloody or infected secretions) from the mouth first and then the nose. Routine suctioning of clear, non-obstructing secretions is unnecessary, and it can cause bradycardia.

Meconium or pus in the amniotic fluid is not an exception to the *airway before breathing* rule. Meconium-stained babies who are vigorous (as evidenced by strong respirations, normal muscle tone, and heart rate  $>100$  beats/minute) have already established an airway and effective breathing, so they need only observation and routine care with the mother. However, meconium-stained babies who are not vigorous (ie, they have suboptimal respirations, muscle tone, or heart rate) may benefit from tracheal intubation and direct suctioning, in addition to clearing of the oropharyngeal airway. Assistance with breathing, whether by stimulation or PPV, should not be given until suctioning has been performed. Suctioning of the airway before delivery of the head does not improve meconium aspiration syndrome or related outcomes in meconium-stained babies. Therefore, routine intrapartum suctioning of such babies by the obstetrician is no longer recommended. Previous practices, such as judging the thickness of the meconium and visualizing the cords to decide whether to intubate, are not supported by evidence.

Approximately 30 seconds after birth, most newborns have been provided with a patent airway, as well as some tactile stimulation through drying. Recurrent

**Figure 109-4** Chart describing general flow of neonatal resuscitation. Endotracheal intubation may be considered at several steps. (Reprinted from Kattwinkel J, Perlman JM, Aziz K, et al. Neonatal Resuscitation: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Pediatrics. 2010;126:e1400-e1413. #### BOX 109-6 Key Questions in Determining the Need for Resuscitation

Was the baby born after full-term gestation?  
Is the baby breathing or crying?

Does the baby have good muscle tone?

evaluation of the dyad of respirations and heart rate is then needed to decide whether resuscitative support should be escalated or abated, in a stepwise manner, at approximately 30-second intervals. An increase in heart rate is the most sensitive indicator of a positive response at each step. Color (or SpO<sub>2</sub>) is additionally used to evaluate oxygenation. Persistent cyanosis may suggest hypoxemia, but when oximetry readings are obtained, SpO<sub>2</sub> should be used because of the unreliability of color assessments.

Indications for immediate institution of PPV include apnea, gasping, or bradycardia (heart rate <100 beats/minute). Adequate inflation and ventilation of the lungs are by far the most essential aspect of resuscitation in the depressed newborn. During the first “golden minute,” the initial steps, reevaluation, and assistance with ventilation, if needed, should all be accomplished.

A higher threshold for oxygen supplementation is a key component of the current NRP recommendations. This is justified by recognition of the gradual transition towards normoxemia over 10 minutes in healthy newborns (Figure 109-1), evidence that resuscitation with air produces results equal or superior to those obtained by resuscitation with oxygen, and concerns with adverse effects of even brief hyperoxia in both term and preterm newborns. Therefore, a newborn who is breathing and has a normal heart rate, but who is cyanotic, should have SpO<sub>2</sub> monitoring and possibly receive respiratory assistance with

continuous positive airway pressure before supplemental oxygen is started.

Breathing support requires devices to assist and monitor ventilation, as well as equipment to deliver and monitor oxygen (Table 109-1). Assisted ventilation necessitates both a positive pressure generator such as a bag or T-piece ventilator and a mechanism to connect this device to the newborn’s airway (eg, facemask, endotracheal tube) (Table 109-2). PPV should begin with air in term neonates or blended oxygen titrated to attain SpO<sub>2</sub> in the time-appropriate target range in preterm neonates.

An additional team member will be needed and should be called for when beginning PPV.

Bag-mask ventilation, a critical skill in resuscitation, is often performed suboptimally. A tight seal between the mask and face is necessary to operate a flow-inflating bag or T-piece resuscitator. However, obstructing the airway by depressing the mandible with the facemask or inadvertently pressing with the free fingers on the submandibular area (see Box 109-2) must be avoided. Deliberately placing the middle and fourth fingers under the chin and the angle of the mandible, respectively, provides a jaw lift and keeps the airway open during ventilation (Figure 109-5).

Effective ventilation is signaled by a slight rise of the chest with each assisted breath, with a consequent rapid increase in heart rate; secondary signs include gradual improvement in oxygenation, return of muscle

**Table 109-1** Equipment for Oxygen Delivery and Monitoring

FUNCTION	DEVICE	COMMENT
Oxygenation monitoring	Pulse oximeter	Allow gradual rise in SpO <sub>2</sub> from 65% to 90% by 10 min of age. Avoid SpO <sub>2</sub> >95%
Adjustable FiO <sub>2</sub>	Oxygen blender	Avoid hyperoxia, particularly in very preterm neonates (<32 wk)
Air source	Wall outlet, tank	—
Oxygen source	Wall outlet, tank	—
Free-flow oxygen conduit	Tubing, mask, with or without bag	Cannot be delivered through a self-inflating bag and mask

FiO<sub>2</sub>, fraction of inspired oxygen; SpO<sub>2</sub>, oxygen saturation by pulse oximetry.

**Table 109-2** Equipment for Assisting and Monitoring Ventilation

FUNCTION	DEVICE	COMMENTS
Pressure generator	Flow-inflating or self-inflating bags, T-piece ventilators	Self-inflating bag can function without a gas source, but cannot deliver PEEP; others need compressed gas (wall outlet, tank) but can deliver PEEP or CPAP.
Pressure conduit into airway	Facemask, endotracheal tube, laryngeal mask airway	Assess appropriate size (and tube depth) before use.
Ventilation monitoring	Carbon dioxide detector; pressure manometer	Tidal volume monitoring would be ideal, but it is not commonly available.

CPAP, continuous positive airway pressure; PEEP, positive end-expiratory pressure.

**Figure 109-5** Positioning of hand to maintain open airway during bag-mask ventilation. The middle and fourth fingers are placed under the chin and the angle of the mandible, respectively, which lifts the jaw. Keeping these fingers on bony landmarks prevents inadvertent compression of submandibular tissue and airway obstruction. The first 2 fingers naturally accommodate the facemask.

tone, and spontaneous breathing. Assisted breaths should be given at a rate of 40 to 60 per minute, at the minimal peak inflation pressure necessary to effect a slight chest movement (most often 20–30 cm H<sub>2</sub>O). The NRP recommends starting PPV with room air or blended oxygen. If blended O<sub>2</sub> is not available, resuscitation should be initiated with air.

Bag-mask ventilation that is ineffective in achieving physiologic improvement should prompt reassessment of the airway (external or internal)-breathing sequence. The physician should reposition the baby's head, lift the jaw, reapply the facemask, check for secretions and suction as needed, increase inflation pressure, and check the bag. When bradycardia persists after 90 seconds of resuscitation, FiO<sub>2</sub> should be increased to 100% until the heart rate normalizes.

Persistently ineffective ventilation should prompt the use of a more reliable airway, either by endotracheal intubation or by insertion of a laryngeal mask airway. This is followed by ventilation and reassessment.

Modifying this sequence of interventions may be appropriate in some circumstances. For example, some very premature infants may benefit from prophylactic surfactant and early use of continuous positive airway pressure; avoidance of hyperoxia is particularly important in this population (Table 109-3).

Chest compressions are indicated when bradycardia (heart rate <60 beats/minute) persists despite effective PPV for 30 seconds. Because of the requirement for effective ventilation and reevaluation, compressions would rarely begin in the first postnatal minute. Chest compressions are preferably performed with the 2-thumb technique, with hands encircling the chest. Ventilation (with 100% oxygen) must remain adequate during chest compressions; thus, intubation is strongly recommended at this point. Chest compressions are carried out in 2-second cycles of 3 compressions followed by 1 breath,

coordinated as the compressor verbalizes “1-and-2-and-3-and-breathe-and . . .”; this technique results in 90 compressions and 30 breaths per minute.

Epinephrine is indicated if the heart rate remains below 60 beats/minute after about 60 seconds of coordinated ventilation and chest compressions. The NRP recommends administration of epinephrine intravenously (Table 109-3), through a shallow umbilical venous catheter, inserted to a depth of 3 or 4 cm. While vascular access is sought, epinephrine may be given once endotracheally at a higher dose (Table 109-3), with the understanding that its absorption from the airway is erratic and its effectiveness uncertain. Epinephrine doses may be repeated every 3 to 5 minutes. Reassessment of heart rate should occur at approximately 1-minute intervals, to minimize interruptions of ventilation and compressions.

### Extensive or Complicated Resuscitation

Because persistent cardiorespiratory depression most often results from ineffective resuscitative efforts, the mechanics of each basic step should be reassessed before further intervention.

The physician should recheck the airway (endotracheal tube position) (Table 109-4), the effectiveness of ventilation (exhaled CO<sub>2</sub>, chest movement, breath sounds), chest compressions, and epinephrine delivery and then consider the possibility of hypovolemia.

If the baby responds poorly to resuscitation and blood loss is suspected (eg, pallor, hypoperfusion, history of abruption placenta, tight nuchal cord with early cord clamping), then hypovolemia is likely. This circumstance is an indication for volume expansion with 1 or more doses of normal saline or lactated Ringer solution. Unmatched O-negative blood may be used immediately if anemia is suspected.

The efficacy and safety of sodium bicarbonate in neonatal resuscitation are uncertain, and its use during brief resuscitations is discouraged.

Naloxone should not be administered during the primary steps of resuscitation. Intrapartum exposure to narcotics causes central apnea, not direct cardiac and neuromuscular dysfunction. Thus naloxone is indicated only after PPV has restored a normal heart rate and color, if respiratory depression continues, and if a history of intrapartum narcotic administration within 4 hours of birth exists.

Continued failure of effective ventilation despite appropriate endotracheal tube placement should raise consideration of airway malformations (see Box 109-2) or inability to inflate the lungs as a result of pneumothorax or diaphragmatic hernia; obvious asymmetry of breath sounds and shifted or muffled cardiac sounds suggest the latter diagnoses. Poor response to resuscitation despite adequate ventilation may indicate primary circulatory insufficiency (see Box 109-4).

Suspected tension pneumothorax, or hydrothorax, in a newborn who responds poorly to resuscitation is an indication for emergency thoracentesis. An 18- or 20-gauge angiocatheter, rather than a butterfly needle, is safe for this purpose. The catheter should be inserted at the fourth intercostal space, anterior axillary line, to drain gas, or at the midaxillary line to drain fluid.

**Table 109-3** Medications for Neonatal Resuscitation in the Delivery Room

MEDICATION	DOSE	ROUTE	INDICATION
Epinephrine (1:10,000, ie, 0.1 mg/mL)	0.1 to 0.3 mL/kg	IV (preferred) A first, higher dose may be endotracheal	Bradycardia persisting after adequate ventilation and chest compressions. Endotracheal dose (0.3–1 mL/kg) optional, while establishing IV access
Volume expander (normal saline, lactated Ringer solution, or blood)	10 mL/kg	IV, slow	Poor response to resuscitation, and suspected blood loss, shock, pallor, hypoperfusion
<i>The medications below have a limited role in neonatal resuscitation; they are not recommended in the immediate delivery room setting.</i>			
Sodium bicarbonate (0.5 mEq/mL)	2 mEq/kg	IV, slow	Prolonged CPR unresponsive to adequate ventilation and other therapies
Naloxone	0.1 mg/kg	IV or IM only (not endotracheal)	After resuscitation (ie, heart rate and color normal), for intrapartum narcotic-induced respiratory depression

CPR, cardiopulmonary resuscitation; IM, intramuscular; IV, intravenous.

**Table 109-4** Endotracheal Tube Size and Depth for Neonates

GESTATIONAL AGE, WK	WEIGHT, G	TUBE INNER DIAMETER, mm	DEPTH OF INSERTION FROM UPPER LIP, cm
23–24	<600	2.5	5.5–6
25–28	600–1,000	2.5	6.5–7
28–34	1,000–2,000	3	7–8
34–38	2,000–3,000	3.5	8–9
39–42	3,000–5,000	3.5–4.0	9–10

### Newborns Unresponsive to Resuscitation

Asystole persisting after 10 minutes of adequate resuscitation, which may be beyond 10 minutes of life, indicates a very low probability of intact survival. Therefore, discontinuing resuscitation and instituting comfort care centered on the family's needs may be appropriate. This decision should be individualized, based on factors such as the underlying prognosis, the presumed causes and potential reversibility of the cardiorespiratory arrest, and the family's feelings regarding acceptable risk for morbidity. Persistent bradycardia unresponsive to adequate resuscitation in a newborn with obvious conditions associated with lung hypoplasia (eg, oligohydramnios sequence, Potter syndrome) would also justify discontinuing resuscitation efforts.

### Technical Considerations of Endotracheal Intubation

Intubation should not be viewed as a step in resuscitation but rather as a method that may be applied during any of the basic steps for distinct indications. It may be used to suction debris from the airway; to establish an artificial airway and enhance ventilation when bag-mask ventilation is ineffective, prolonged, or inadvisable (eg, diaphragmatic hernia, gastroschisis); or to administer drugs such as surfactant.

Experts suggest that a physician capable of performing endotracheal intubation be available at every delivery. In addition to appropriately sized endotracheal tubes, a laryngoscope with a No. 0 blade for a preterm newborn or a No. 1 blade for term newborns is essential. The following tips are intended to improve efficacy and safety of intubation.

Intubation of a main-stem bronchus is a common event that can result in ineffective ventilation and other serious complications. Thus, the physician should explicitly designate both endotracheal tube size and intended depth of insertion before attempting intubation. The depth of endotracheal tube insertion can be estimated from actual or expected weight, as noted in Table 109-4. Alternatively, Tochen's rule (6 + weight in kg = tip-to-lip depth in cm) is easy to memorize, although inaccurate in extremely preterm neonates. Appropriate endotracheal tube insertion depth should first be guided by visually placing the vocal cord mark on the tube at the level of the vocal cords; external depth at the lip should then be verified using the length (cm) marks on the tube, before assisted ventilation is initiated. At ventilation, confirmation of endotracheal tube placement in the trachea should rely primarily on finding an increasing heart rate and exhaled carbon dioxide by using a carbon dioxide detector. Other useful methods of verifying endotracheal tube placement, such as observing chest rise, condensation in the tube,

skin color, or auscultation of breath sounds, are less reliable. If the endotracheal tube is to remain in place after resuscitation, then a radiograph should be obtained to verify tube position.

The NRP now recognizes the laryngeal mask airway as an alternative device to assist ventilation in newborns of at least 34 weeks' gestation who cannot be effectively managed by bag-mask ventilated or endotracheal intubation. These devices are simple to use, but experience with their application in neonatal resuscitation is still limited.

### Special Considerations for Premature Newborns

Preterm babies, especially those who are very premature ( $\leq 28$  weeks' gestation), have special needs during and after resuscitation, as detailed previously and summarized in Table 109-5.

Physicians will note the new NRP emphasis on more strict management of oxygenation during neonatal resuscitation, particularly in preterm newborns. This action was prompted by preliminary clinical and laboratory evidence suggesting deleterious effects of even brief exposures to hyperoxia and equivalent effectiveness and resuscitation with room air or 100% oxygen. Present NRP guidelines do not indicate a specific initial  $\text{FiO}_2$  for assisting ventilation in very preterm newborns ( $< 32$  weeks), but 30% to 40%  $\text{FiO}_2$  is commonly used in practice. Using pulse oximetry monitoring and an oxygen blender during resuscitation, the physician can titrate  $\text{FiO}_2$  to increase  $\text{SpO}_2$  gradually toward 90% over 10 minutes.  $\text{FiO}_2$  should be decreased if oxygen saturations exceed 95%. In the presence of bradycardia, appropriate ventilation with 100% oxygen is indicated.

For full-term newborns, the NRP guidelines recommend administering initial PPV using room air, without

the immediate need for pulse oximetry monitoring. However, experts recognize that alternative approaches may be reasonable.

## POSTRESUSCITATION ASSESSMENT AND STABILIZATION

After initial stabilization, a more detailed assessment of the baby's condition and evaluation of relevant risk factors in the prenatal history (see Box 109-1) should be undertaken to guide further care.

Acute postresuscitation derangements in cardiorespiratory, neurologic, and metabolic function should be sought. Reexamining the ABCs is a simple strategy to ensure sustained adequate ventilation and perfusion in addition to thermoregulation. A malpositioned endotracheal tube, large pneumothorax, or acute hypovolemia after fetoplacental transfusion can cause further physiologic derangements. Frequent monitoring of vital signs is useful. However, blood pressure may remain normal despite insufficient systemic or pulmonary blood flow, which would be evident as peripheral hypoperfusion and hypoxemia, respectively. Newborns who were significantly depressed need to be evaluated for acute metabolic complications such as hypoglycemia or severe acidosis.

Preexisting conditions, such as maternal diabetes, fetal growth restriction, significant dysmorphisms found by obstetric ultrasound or during physical examination, and risk factors for sepsis, require specific diagnostic and therapeutic interventions shortly after birth.

Some congenital malformations require specific attention during stabilization. For example, relief of airway obstruction caused by Pierre Robin sequence can be accomplished by prone positioning and a nasopharyngeal airway.

**Table 109-5** Special Needs of Preterm Newborns During Resuscitation

SPECIAL FEATURE OF PRETERM NEWBORNS	ADJUSTMENT TO RESUSCITATION PROCEDURES
Thermoregulation: rapid heat loss	Avoid convective and evaporative losses. Use plastic wrap when infant is $\leq 28$ weeks' gestation.
Fragile skin, particularly at $< 25$ weeks' gestation	Avoid rubbing. Use protective barriers when taping or otherwise securing devices onto skin.
Diminished respiratory drive	Low threshold for supporting ventilation. Need physician skilled at intubation.
Likely surfactant deficiency	May benefit from prophylactic surfactant.
Lungs susceptible to immediate ventilatory injury	Provide continuous positive airway pressure or the minimal inflation pressures needed to support adequate ventilation and oxygenation.
Tissue vulnerability to hyperoxic injury	Use oxygen blender, pulse oximetry to attain $\text{SpO}_2$ between 85% and 95% by 10 minutes of age. Start resuscitation with an oxygen concentration $< 100\%$ (eg, 30%–40%).
Susceptibility to brain hemorrhage and/or ischemia	Avoid hyperventilation, hypocapnia, and rapid infusion of fluid boluses or hypertonic solutions.
Metabolic susceptibility to hypoglycemia	Monitor for hypoglycemia.
Susceptibility to infection	Assess risk for infection. Many preterm newborns $< 35$ weeks' gestation need an evaluation for sepsis immediately after birth, and possibly empirical antibiotic therapy, pending diagnostic tests.

$\text{SpO}_2$ , oxygen saturation by pulse oximetry.

Anomalies characterized by exposed internal organs, such as gastroschisis, meningocele or other neural tube defects, and cloacal exstrophy, necessitate protection from heat and fluid loss, contamination by environmental microorganisms, and traumatic or ischemic injury. Immediate enclosure in a sterile plastic bag safeguards tissues from evaporation and infection. Generally, the newborn should be positioned so as to optimize blood flow to the structures. This goal can be achieved by keeping pressure off the anomaly and by keeping arterial and venous supply to the lesion unobstructed; a newborn with a gastroschisis, for example, would best be stabilized in the right lateral decubitus position. Finally, the newborn should be protected from excessive, unnecessary examinations, and appropriate pain management should be provided if needed.

## UMBILICAL CORD BLOOD GAS ANALYSIS

Identifying newborns at risk for complications from intrapartum asphyxia is an issue of significant concern to obstetric and pediatric primary care physicians. The use of arterial umbilical cord acid-base status to define the degree of fetal acidemia that correlates with a high risk for neonatal complications has been the focus of ongoing research efforts. Umbilical arterial or venous blood gases or an early neonatal arterial base deficit (before administration of volume or bicarbonate [no longer recommended]) have been studied for their utility in delineating the degree of acidosis at the time of delivery. Umbilical arterial cord blood gas analysis provides the best information regarding fetal status, whereas umbilical venous cord blood reflects placental functioning most directly. When extensive delivery room resuscitation is necessary, an umbilical venous blood-gas analysis can also be obtained from the newborn immediately on insertion of the umbilical venous catheter.

Neonatal complications are associated with fetal metabolic acidosis, rather than respiratory acidosis; even brief cord compression will produce significant hypercarbia. Therefore, interpretation of umbilical cord pH should include consideration of both respiratory and metabolic components. Although umbilical arterial pH identifies an infant at potential risk for short-term neonatal morbidity, it does not distinguish the infant at risk for a poor long-term outcome. Among infants exhibiting severe hypoxic-ischemic encephalopathy,

fetal hypoxemia is found to be the cause in less than 25% of cases studied. Umbilical arterial pH is normal in 80% of infants experiencing perinatal compromise. Box 109-7 lists the causes of acidosis in infants.

At delivery, the mean umbilical arterial base deficit is 4 to 5 mmol/L. Lackman et al have reported on umbilical cord blood gases in relation to birth size (appropriateness of growth for gestational age) from a population of nearly 30,000 term infants born over a 10-year period (1990–1999) in Canada. The investigators found that the mean pH was  $7.26 \pm 0.07$  and the mean base deficit was  $4.7 \pm 2.9$  mmol/L in umbilical arterial cord blood specimens. Among infants with intrauterine growth restriction, the base deficit was  $5.3 \pm 3.1$ , whereas large-for-gestational-age babies exhibited base deficits of  $4.4 \pm 2.8$  mmol/L.

The degree of metabolic acidosis that determines the threshold for *potential* injury is defined as greater than 2 standard deviations from the mean (10–12 mmol/L) and is accepted as greater than 12 mmol/L. Base deficit levels exceeding 12 mmol/L occur in less than 2% of a normal obstetric population. Also important to note is that most newborns with a base deficit greater than 12 mmol/L do not demonstrate neurologic injury. Among symptomatic infants experiencing severe metabolic acidosis with base deficits greater than 16 mmol/L, most either die or have neurodevelopmental morbidities. In contrast to the symptomatic infant who requires resuscitation and has evidence of a significant metabolic acidosis, the approach to the baby who seems to be transitioning without difficulty but is found to have a base deficit greater than 12 mmol/L is less clear. At a minimum, in addition to a thorough physical assessment for signs of illness or transitional delay, a blood gas analysis should be obtained from the infant to ascertain the persistence of metabolic acidosis or other abnormality necessitating further evaluation or intervention. In the absence of significant hypoxemia or hypothermia, metabolic acidosis that is present at birth and persists is likely caused by circulatory insufficiency resulting most likely from hypovolemia.

The availability of umbilical cord blood gases will depend on the individual hospital policy. Although experts have argued that umbilical cord blood acid-base determination does not add to the evaluation of the vigorous term infant who is assessed to have normal Apgar scores, the medical-legal climate is such that some obstetric societies and hospitals in North

### BOX 109-7 Causes of Acidosis in Neonates

- Respiratory distress<sup>a</sup>
- Sepsis
- Hypovolemia<sup>a</sup>
- Hypothermia<sup>a</sup>
- Severe anemia<sup>a</sup>
- Low cardiac output (hypotension) with poor tissue perfusion
- Cardiac failure
- Perinatal asphyxia<sup>a</sup>
- Inborn errors of metabolism
- Renal bicarbonate losses

<sup>a</sup>These conditions are relevant during delivery room resuscitation.

America and Europe are recommending the routine surveillance of umbilical arterial cord blood gases for all births.

### DELAYED UMBILICAL CORD CLAMPING

Clamping of the umbilical cord shortly after birth is a historically recent practice that is challenged by substantial new evidence. Early cord clamping usually occurs by 15 seconds after birth, whereas the definition of delayed cord clamping has varied among studies, ranging from 30 seconds to 3 minutes after birth, or even to cessation of pulsations in the cord. Multiple studies have shown that early cord clamping interrupts the normal fetoplacental transfusion, resulting in a blood volume deficit of 15 to 20 mL/kg birth weight compared with newborns whose cord clamping was delayed. Systematic reviews have shown improved iron status in infancy after delayed cord clamping in term neonates. In preterm neonates with uncomplicated births, good-quality evidence reveals functional benefits of delayed cord clamping, including higher blood pressures during stabilization, the need for fewer blood transfusions, a lower incidence of intraventricular hemorrhage, and improved development in infancy; these benefits outweigh an increased need for phototherapy with delayed cord clamping. There is insufficient information to evaluate the risks and benefits of delayed cord clamping in the neonates who require resuscitation. Consequently, the NRP recommends delaying umbilical cord clamping for at least 1 minute in newborn infants who do not require resuscitation, while withholding specific recommendations on timing of cord clamping in babies requiring resuscitation. ACOG recently recommended delaying cord clamping in preterm infants, when feasible; this statement has been endorsed by the AAP. Practical consequences of these recommendations include the need for delaying the transfer of the baby between the obstetrician and the neonatal team, and minor alterations in umbilical cord blood gas values, if these are obtained. Recent studies suggest that active milking of the cord may accelerate placental transfusion and yield benefits similar to delayed cord clamping in preterm neonates. These interventions highlight the importance of coordination between the obstetric and neonatal teams in order to optimize outcomes for the neonate.

### DISPOSITION

Depending on the level of support provided to a newborn during resuscitation (see Figure 109-4), subsequent care may be routine or observational (more frequent evaluation in the delivery room or designated observation area), or it may involve postresuscitation care in a special care nursery.

The management of newborns with significant perinatal depression and those whose underlying conditions impart a risk for physiologic instability should be discussed with a neonatologist, and referral to a neonatal intensive care unit may be necessary. Technically challenging interventions such as surfactant administration in the delivery room or the initiation of therapeutic hypothermia should be planned in conjunction with the regional center. After delivery room resuscitation, therapeutic hypothermia should be considered for infants born at 36 weeks' gestation or later with an

umbilical arterial cord gas or arterial pH less than 7.0 or respiratory depression persisting for 10 minutes, because these infants are at risk for evolving hypoxic-ischemic encephalopathy.

### COMMUNICATION AND DOCUMENTATION

After resuscitation interventions, a discussion should take place with the parents, nursing staff, and obstetrician regarding assessment of the newborn and development of a postresuscitation plan of care.

Documentation of these activities is essential. This task is facilitated by the use of structured forms that help guide the flow of resuscitation while rapidly recording evaluations and interventions at appropriate time intervals and even the corresponding orders. Attribution of Apgar scores, whether performed concurrently by an observer or in retrospect, is more meaningful if the signs assessed are recorded together with concurrent interventions. An expanded Apgar score form has been proposed for this purpose.

### EVALUATION AND QUALITY IMPROVEMENT IN NEONATAL RESUSCITATION

Neonatal resuscitation is a critical activity amenable to perinatal quality assurance and quality improvement. The performance of both individual physician and the team can be improved by incorporating techniques such as simulation, team training, checklists, and habitual team briefing plus debriefing around actual resuscitations. Measures related to both the resuscitation process and immediate outcomes may be useful in characterizing the effectiveness, efficiency, and timeliness of resuscitative interventions, even if only in high-risk subgroups (eg, very-low-birth weight, meconium staining). The variables to be tracked should depend on the specific questions to be answered about each institution's neonatal stabilization procedures. However, a few measures reflect efficacy and safety in core processes; they may be particularly useful if they are easy to collect and if published benchmark data are available. For example, in newborns with very low or extremely low birth weight, record the proportion given chest compressions, epinephrine, or both; the time to first surfactant dose and admission temperature; in all newborns, note the number of intubation attempts and the proportion of endotracheal tubes.

Maintaining a highly effective recording system for neonatal resuscitation requires not only maintenance of infrastructure and recurrent training and updating of personnel, but also a planned, systematic evaluation of procedures in high-risk cases and sentinel events. Both intramural evaluations and external benchmarking in conjunction with the regional perinatal center are necessary elements of this process.

## Chapter 110

# IDENTIFYING THE NEWBORN WHO REQUIRES SPECIALIZED CARE

Upender K. Munshi, MBBS, MD

Full-term newborn infants after a normal spontaneous vaginal delivery are usually assessed by the delivery room nurse, who may notify the primary care physician (PCP) if any abnormality of cardiorespiratory adaptation or any external malformations are observed. The PCP or nurse practitioner who attends a high-risk delivery will typically perform a brief assessment of the newborn after birth. After this initial assessment, a

decision is made whether the baby is stable enough to remain with the mother and continue to receive couplet care or if the infant requires specialized newborn care in a transitional, special care or neonatal intensive care unit (NICU).

## NEWBORNS TYPICALLY CARED FOR IN A NEONATAL INTENSIVE CARE UNIT

Most newborns who are referred to a NICU fall into 1 of 3 broad categories: infants who have a clear need for neonatal intensive or critical care; those with a possible need for NICU care, and; infants with a normal initial assessment but who have warning signs in their prenatal history/maternal lab results, postnatal examination findings, or newborn screening labs (Box 110-1).

### Clear Need for Neonatal Intensive Care Unit Care

The decision-making process for referral to a higher level of care is straightforward in this group. Referral to the NICU should be initiated immediately while the initial diagnostic and therapeutic measures commence.

### Possible Need for Neonatal Intensive Care Unit Care

For newborns who have borderline maturity, mildly abnormal physical findings, or borderline laboratory results, making the decision for referral to NICU will depend on the level of care and resources available at the place of birth. For level I hospitals with basic newborn care, it is a relatively easy decision to initiate transfer to the higher-level facility after consulting with the accepting neonatologist; however, for pediatricians and neonatologists covering level II or higher hospitals, referral to regional NICU may not be that easy a decision. In addition, some newborns exhibit grunting, flaring, and chest wall retractions within minutes after birth, which results in an early transfer to NICU. These transient respiratory symptoms frequently subside within first few hours, often during the transport itself, making such transfers from level II or higher hospitals to the regional NICU unnecessary.

These transfers cause parental anxiety and interruption in the newborn–parent bonding, particularly when it involves transfer to another hospital. Watchful observation in consultation with the regional NICU attending physician and communication of clinical or laboratory parameters for a reasonable amount of time is appropriate. This communication can avert an unnecessary NICU admission as well as prevent delay in NICU transfer of infants who need neonatal intensive care.

### Well-Seeming Infants and Neonatal Intensive Care Unit Care

For most infants who are vigorous and appear well at birth, no higher level care will be required. However, occasionally a baby in this group may have warning signs in the prenatal or postnatal history, subtle findings in the physical examination, or concerning laboratory results that need to be addressed.

### BOX 110-1 Broad Categories of Newborns for Neonatal Intensive Care Unit (NICU) Referral

Group 1: Clear need for NICU care (*Call NICU early; start appropriate diagnostic and therapeutic measures and arrange prompt transfer if the necessary neonatal level of care is not available on-site*)

- Very low-birth-weight infants <1,500 g, or gestation <34 weeks
- Moderate to severe respiratory distress at birth or any time afterward
- Sepsis syndrome: temperature or cardiorespiratory instability, lethargy, mottling of skin, respiratory distress
- Compromised cardiovascular function, central cyanosis, moderate to severe metabolic acidosis
- Hypoxic ischemic encephalopathy, neonatal seizures
- Severe hemolytic anemia, erythroblastosis fetalis, hydrops
- Life-threatening malformations such as gastroschisis, diaphragmatic hernia, prenatal diagnosis of duct-dependent congenital heart disease

Group 2: Possible need for NICU (*Communicate and discuss with regional NICU team if delivery occurs at a level I hospital*)

- Borderline maturity (34-37 weeks' gestation) and birth weight just below the acceptable limits for a community hospital (<2,000 g)
- Transitional issues, including mild to moderate respiratory distress within first hours after birth on low respiratory support
- Infant with vomiting or abdominal distention, non-passage of meconium >24 hours after birth
- Cord blood bilirubin more than 4 mg/dl, onset of jaundice during the first 24 hours, and rapidly rising serum bilirubin

Group 3: Infants with a normal initial assessment (*Review history, physical examination, and laboratory results. Watch for any warning signs*)

- Infants at risk for neonatal hypoglycemia (infant of diabetic mother, late preterm infant, small-for-gestational-age infant)
- Infants at risk for sepsis (maternal fever, prolonged rupture of membranes, chorioamnionitis, GBS positive mother with no or inadequate prophylaxis)
- Abnormal finding on prenatal sonography, such as suspected ovarian cyst, echogenic dilated bowel, hydronephrosis, ventriculomegaly
- Infant with borderline results of pulse oximetry screening for congenital heart disease

## REFERRAL FOR NEONATAL INTENSIVE CARE

The objective of this chapter is to present a systematic approach for the PCP to identify newborns in the 2 categories who may require admission to NICU for close monitoring and management. Early recognition of these conditions may help with timely referrals and avert complications resulting from delayed transfer of patients. In addition, factors other than the actual medical condition of the newborn may come into play while

### BOX 110-2 Initial Workup of an Ill-Seeming Newborn

- Vital signs, including 4-limb blood pressures
- Pulse oximeter oxygen saturation (SpO<sub>2</sub>), pre- and postductal
- Rapid point-of-care blood glucose testing using a glucose strip test (Dextrostix) or glucometer
- Blood cell counts: hematocrit and hemoglobin, white cell count with differential, platelet count
- Basic metabolic panel: serum glucose, electrolytes, calcium, urea nitrogen, creatinine
- Umbilical cord blood gases (pH and base deficit), if available
- Blood gas and chest radiograph, deferring if no respiratory distress
- Blood culture, deferring if low risk of infection
- If SpO<sub>2</sub> or arterial pressure of oxygen in room air is low (<90%), then observe the response to 100% oxygen (hyperoxia test)

If an inborn error of metabolism is suspected, blood should be sent for lactate, pyruvate, ammonia, plasma amino acid profile, carnitine, and acylcarnitine. Also test urine for organic acids and reducing substance. Keep extra samples of blood and urine for specific genetic tests and store at 68°F (20°C).

referrals of the newborn to other hospitals are made. These factors, not discussed in this chapter, may include training and competence of the PCP in the field of newborn medicine; the PCP's experience of an adverse outcome in a previous case; availability of around-the-clock, in-hospital physician coverage; time restrictions; financial implications of the commitment to ambulatory patient care; adequacy and comfort level of the nursing staff; and third-party payer characteristics.

To assess a newborn properly, the PCP must review the mother's medical, pregnancy, and intrapartum history and delivery course, including results of screening laboratory tests and any imaging studies. A newborn exhibiting signs of illness should have an initial workup (Box 110-2) that may facilitate early recognition of problems and more timely consultation with or referral to the NICU.

## COMMON CONDITIONS REQUIRING NEONATAL INTENSIVE CARE

### The Immature Infant

Increased morbidity and mortality in preterm infants is inversely proportional to the degree of gestational maturity. Every state health care system has attempted to classify newborn care facilities into levels of care so that the care provided by each hospital appropriately matches with the needs of infants of varying gestation and severity of illness, leading to the concept of regionalized perinatal care. In order to have uniform definitions of levels of care and standard nomenclature for health care providers and state public health care systems, the American Academy of Pediatrics (AAP) Committee on Fetus and Newborn (COFN) has provided guidelines and recommendations in their policy statement from 2012

**Table 110-1** Definitions, Capabilities, and Provider Types: Neonatal Levels of Care

LEVEL OF CARE	CAPABILITIES	PROVIDER TYPES <sup>a</sup>
Level I Well newborn nursery	<ul style="list-style-type: none"> <li>• Provide neonatal resuscitation at every delivery</li> <li>• Evaluate and provide postnatal care to stable term newborn infants</li> <li>• Stabilize and provide care for infants born at 35 to 37 weeks' gestation who remain physiologically stable</li> <li>• Stabilize newborn infants who are ill and those born at less than 35 weeks' gestation until transfer to a higher level of care</li> </ul>	Pediatricians, family physicians, physician assistants, pediatric or family nurse practitioners, and other advanced practice registered nurses
Level II Special care nursery	Level I capabilities plus: <ul style="list-style-type: none"> <li>• Provide care for infants born at 32 or more weeks' gestation and weighing 1,500 g or more who have physiologic immaturity or who are moderately ill with problems that are expected to resolve rapidly and are not anticipated to need subspecialty services on an urgent basis</li> <li>• Provide care for infants convalescing after intensive care</li> <li>• Provide mechanical ventilation for brief duration (&lt;24 hours) or continuous positive airway pressure or both</li> <li>• Stabilize infants born before 32 weeks' gestation and weighing less than 1,500 g until transfer to a neonatal intensive care facility</li> </ul>	Level I health care providers plus: Pediatric hospitalists, neonatologists, and neonatal nurse practitioners
Level III NICU	Level II capabilities plus: <ul style="list-style-type: none"> <li>• Provide sustained life support</li> <li>• Provide comprehensive care for infants born at less than 32 weeks' gestation and weighing less than 1,500 g and infants born at all gestational ages and birth weights with critical illness</li> <li>• Provide prompt and readily available access to a full range of pediatric medical subspecialists, pediatric surgical specialists, pediatric anesthesiologists, and pediatric ophthalmologists</li> <li>• Provide a full range of respiratory support that may include conventional or high-frequency ventilation and inhaled nitric oxide</li> <li>• Perform advanced imaging with interpretation on an urgent basis, including computed tomography, MRI, and echocardiography</li> </ul>	Level II health care providers plus: Pediatric medical subspecialists, <sup>b</sup> pediatric anesthesiologists, <sup>b</sup> pediatric surgeons, and pediatric ophthalmologists <sup>b</sup>
Level IV Regional NICU	Level III capabilities plus: <ul style="list-style-type: none"> <li>• Located within an institution with the capability to provide surgical repair of complex congenital or acquired conditions</li> <li>• Maintain a full range of pediatric medical subspecialists, pediatric surgical subspecialists, and pediatric anesthesiologists at the site</li> <li>• Facilitate transport and provide outreach education</li> </ul>	Level III health care providers plus: Pediatric surgical subspecialists

<sup>a</sup>Includes all providers with relevant experience, training, and demonstrated competence<sup>b</sup>At the site or at a closely related institution by prearranged consultation agreementFrom American Academy of Pediatrics Committee on Fetus and Newborn. Levels of neonatal care. *Pediatrics*. 2012;130(3):587–597.

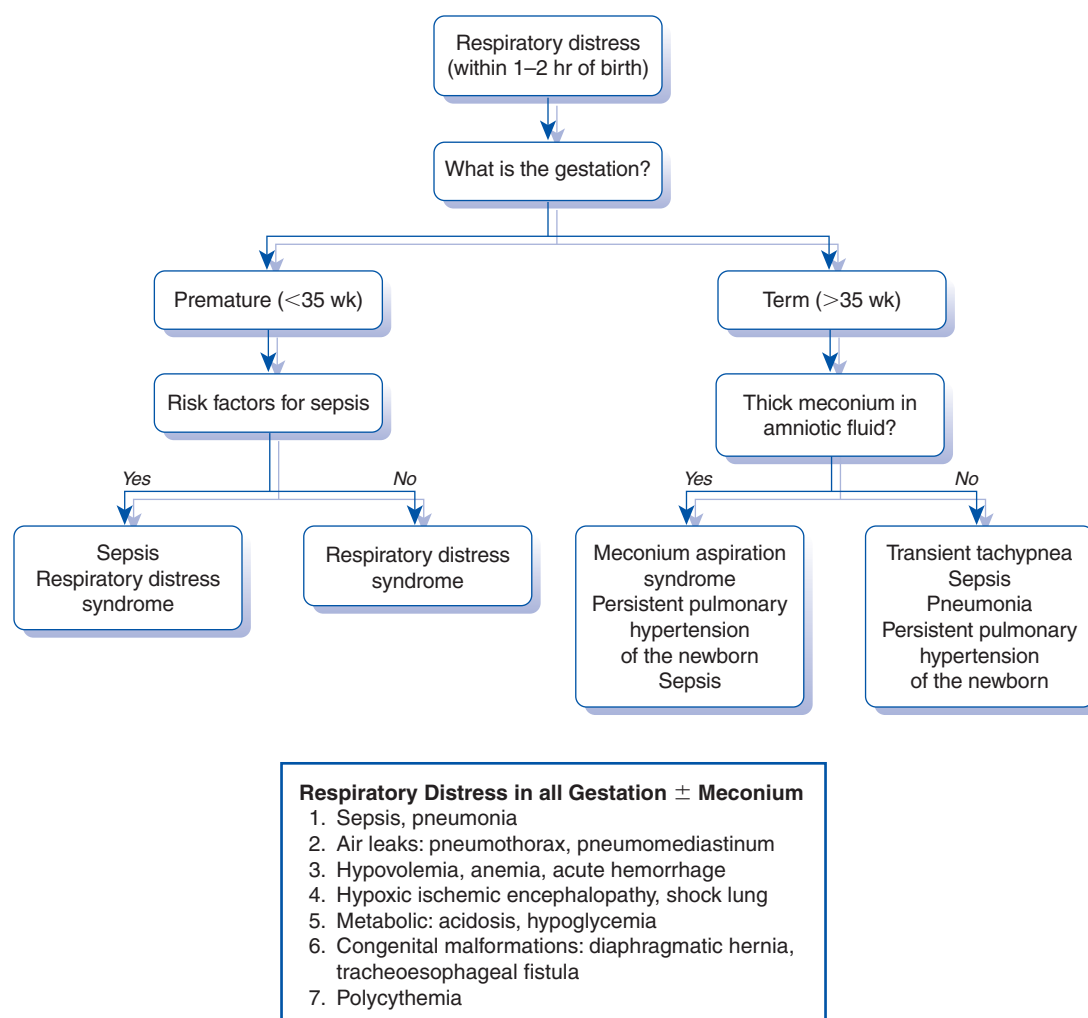

(Table 110-1). According to this statement, neonatal levels of care are provided at 4 levels: Level I (Well Newborn Nursery), Level II (Special Care Nursery), Level III (Neonatal Intensive Care Unit: NICU), and Level IV (Regional NICU), depending on capabilities and the provider type at each level.

Resources at level II and III hospitals may vary significantly; therefore, each hospital should have guidelines (conforming to AAP guidelines, respective state health department regulations, and their own available resources) for gestation and birth weight cutoffs

below which affected preterm or low-birth-weight infants should be referred for a higher level of care.

### Respiratory Distress

Common causes of respiratory distress within the first few hours of life are listed in Figure 110-1 (see also Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn). Increased respiratory rate and work of breathing, as characterized by breathing rates of more than 60 breaths per minute, grunting, nasal flaring, and chest wall retractions, are the findings that

**Figure 110-1** Respiratory distress within the first few hours of life.

typically prompt evaluation and intervention. If these signs are accompanied by central cyanosis or the need for supplemental oxygen to maintain normal color or pulse oximeter saturations, then it may indicate an underlying disorder that requires immediate diagnostic and therapeutic intervention. Presence of these signs in a preterm newborn suggests respiratory distress syndrome caused by surfactant deficiency. Similar manifestation in a term or late preterm newborn may be the result of transient tachypnea of newborn (TTN) if the amniotic fluid is clear and the delivery is by cesarean. Respiratory distress that improves with each hour and resolves in approximately 24 hours is caused by TTN, whereas worsening or persisting respiratory distress beyond 24 hours rules out this diagnosis. Respiratory distress with presence of thick meconium-stained fluid points toward meconium aspiration syndrome, which is especially common in postterm infants who require resuscitation at delivery. These infants usually have meconium staining of nails and umbilical cord. Meconium aspiration syndrome is invariably associated with persistent pulmonary hypertension of newborn, which makes the respiratory failure worse and difficult to manage.

An infant exhibiting signs of respiratory distress persisting beyond the initial 20 to 30 minutes after delivery at level I (community) hospitals should be considered for transfer to a higher level of care. At level II (special care nursery), infants with mild to moderate respiratory distress diagnosed to be TTN after review of chest radiograph can be managed on continuous positive airway pressure (CPAP), with the regional NICU team consulted to follow up on the progress. Those infants who do not improve in 12 to 24 hours and continue to require an increasing fraction of inspired oxygen need to be transferred to a NICU. Neonates with respiratory distress resulting from causes other than TTN should be transferred to level III (NICU); see Box 110-1 depicting guidelines from the COFN statement. All other categories of respiratory distress needing invasive ventilatory support should result in transfer to a higher level of care.

### Sepsis Syndrome

Sepsis mimics most of the neonatal systemic disorders that affect newborns of all gestational ages, and its onset can span from the delivery room to anytime thereafter. Risk factors for neonatal sepsis, such as

maternal fever, chorioamnionitis, prolonged rupture of membranes, urinary tract infections, group B *Streptococcus* colonization, or a history of genital herpes, should be sought in the maternal history. In the delivery room, sepsis syndrome occurs mostly in the form of respiratory distress and cardiovascular instability in the form of tachycardia; pale, mottled skin; delayed capillary refill; and hypotension. Later onset is demonstrated by a change in the baby's baseline behavior, such as poor feeding, irritability, and lethargy, as well as temperature instability in a baby who had been having apparently normal activity and feeding pattern. Skin or mucous membrane lesions should be examined for the possibility of neonatal herpes; negative maternal history of genital herpes does not rule out neonatal herpes infection (see Chapter 102, The Newborn at Risk for Infection). Physicians need to recognize these changes early enough to initiate diagnostic (biochemical and hematologic studies, body fluid cultures) and therapeutic interventions (intravenous antibiotics) promptly, and physicians at level I and level II hospitals should simultaneously initiate referral to a higher level of care. Blood cell counts are often checked to find evidence for or against the diagnosis of neonatal sepsis; however, these results should be interpreted judiciously and not relied on as the sole factor for decision making. Neutropenia in the absence of pregnancy-induced hypertension or preeclampsia syndrome is worrisome, as is a marked left shift with ratio of immature neutrophils (band forms) to total neutrophils (bands plus segmented neutrophils) of 0.3 or more. Elevated C-reactive protein (CRP) as an acute phase reactant in response to infection supports the diagnosis of sepsis. Repeating CRP levels 24 to 48 hours after initiating empirical antibiotics may increase the negative predictive value of the test in ruling out sepsis. In a culture-proven or culture-negative presumed sepsis treated with antibiotics, declining CRP levels have been used to guide the duration of antimicrobial treatment. Use of other cytokines in diagnosis of sepsis like interleukin 6 (IL6) or interleukin 8 (IL8) are still investigational at this time. A combination of CRP and IL6 may provide additional accuracy for differentiation between septic and nonseptic newborn infants during the first 24 hours of suspected sepsis.

### **Infants at Risk for Hypoxic Ischemic Encephalopathy and Multiorgan Involvement**

Newborns with severe cardiorespiratory compromise at birth that requires sustained resuscitation, including intubation, positive pressure ventilation, chest compressions, or epinephrine, are potentially at risk for hypoxic ischemic encephalopathy. These infants should be carefully monitored and their clinical status discussed with the regional NICU team attending. The objective evidence of hypoxic ischemic encephalopathy is based on an umbilical arterial cord pH of less than 7.0, a 5-minute Apgar score of 3 or less, and abnormal neurologic examination (hyper- or hypotonia, irritability, seizures) and involvement of another major organ system. The other organ systems most commonly involved are kidneys, myocardium, lungs, and gastrointestinal tract.

Infants meeting the criteria for hypoxic ischemic encephalopathy should be considered for therapeutic

hypothermia (head cooling or generalized body cooling) (see Figure 110-2) and promptly arranged for transfer to NICU so that cooling is initiated within 6 hours of birth as per current standards. Because of the time constraint on initiating therapeutic hypothermia, within 6 hours, low cord pH of less than 7.0, metabolic acidosis of more than 16, negative base excess with prolonged delivery room resuscitation, and abnormal neurological examination are considered indications for starting head/body cooling since other major organ system dysfunction may not manifest fully within the first few hours. These infants also need ventilatory, metabolic, and nutritional support, as well as neurologic evaluation and seizure control.

Umbilical cord blood gases (UBCG) can help in ascertaining the type (chronic vs acute) and degree of fetal compromise in utero before the delivery. Carbon dioxide diffuses rapidly across the placenta whereas organic acids from metabolism are cleared relatively slowly; therefore, the presence of significant metabolic acidosis (base excess greater than  $-15$ ) is considered as evidence of significant compromise of fetal circulation and should be discussed with the referral NICU attending. After an aggressive resuscitation, newborns who do not strictly meet these criteria but who have abnormal neurologic examination findings or seizures should also be referred to a neonatal intensive care unit for further neurologic evaluation and monitoring.

### **Common Metabolic Derangements**

Common metabolic derangements with early onset (within day 1 or 2 of life) are hypoglycemia, metabolic acidosis, hypocalcemia, hypo- or hypernatremia, and hypo- or hyperkalemia.

Hypoglycemia is the most common metabolic derangement, mostly seen in large-for-gestational-age infants of diabetic mothers (IDM). This derangement is the result of hyperinsulinemia as in IDM infants or, because of depleted glycogen stores, in small-for-gestational-age (SGA) infants. These babies should be routinely monitored by rapid blood glucose strip test. Rarely, hypoglycemia can be the result of inborn error of carbohydrate metabolism (see Chapter 363, Hypoglycemia, and Chapter 106, Specific Congenital Metabolic Diseases). Hypocalcemia is a common problem sometimes seen in infants of diabetic mothers or in situations in which maternal hypercalcemia is present causing transient suppression of fetal parathyroid function. Occasionally, early persistent hypocalcemia may be a clue to DiGeorge syndrome. Early hyponatremia may reflect maternal fluid overload or neonatal fluid overload particularly after administering electrolyte-free, intravenous dextrose solution to newborns beyond the first day of life.

### **Cardiovascular Malformations**

Very few cardiac malformations manifest clinically in the delivery room, such as transposition of great vessels with intact septum, and total anomalous pulmonary venous return may present with respiratory distress and cyanosis at birth or within the first few hours of life. The most common manifestation of serious cardiac malformation coincides with the closure of the ductus

**A Gestational Age  $\geq 36$  weeks****B Physiologic criteria (either of 2)**

- pH  $\leq 7.0$  or base deficit  $\geq 16$  mmol/L  
[on cord blood gas or neonatal ( $<1$  hr old) blood gas]
- pH 7.01 to 7.15 or base deficit 10 to 15.9 mmol/L or no blood gas available.

And

1. Acute perinatal event (late or variable decels, cord prolapse or rupture, uterine rupture, maternal trauma / hemorrhage / cardiorespiratory arrest)
2. 10 minutes Apgar  $\leq 5$   
or  
assisted ventilation at birth—continued for at least 10 minutes

**C Neurologic criteria (either of 2)**

- Signs of moderate to severe encephalopathy on at least 3 of 6 categories; (see table)
- Presence of seizures

**Exclusion Criteria:**

- $>6$  hours old
- Major congenital anomaly
- Severe IUGR (birth weight  $\leq 1,800$  g)

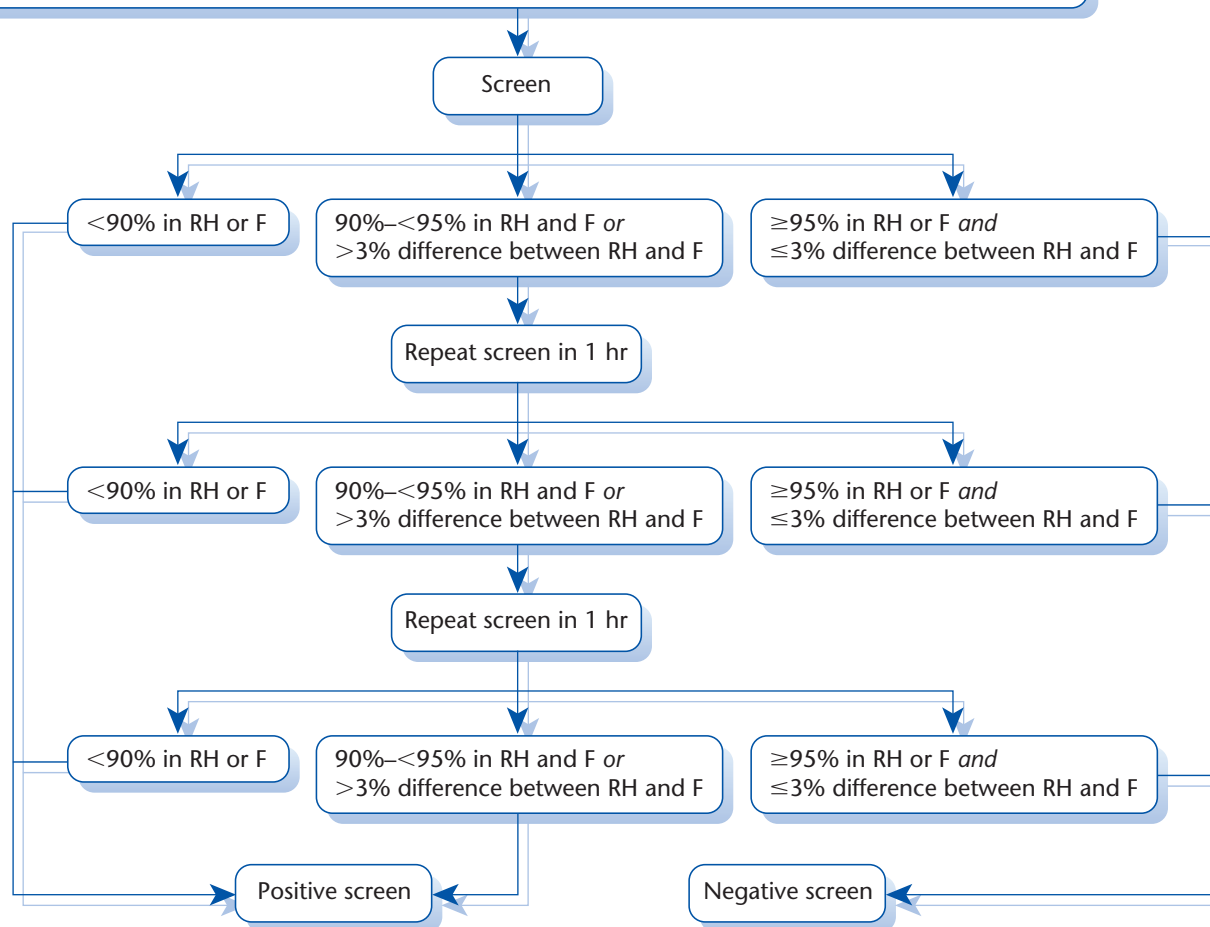

Criteria for Defining Moderate and Severe Encephalopathy		
Category	Moderate Encephalopathy	Severe Encephalopathy
Level of consciousness	Lethargic	Stupor or coma
Spontaneous activity	Decreased activity	No activity
Posture	Distal flexion, complete extension	Decerebrate
Tone	Hypotonia (focal or general)	Flaccid
<i>Primitive reflexes</i>		
Suck	Weak	Absent
Moro	Incomplete	Absent
<i>Autonomic system</i>		
Pupils	Constricted	Deviated, dilated or nonreactive to light
Heart rate	Bradycardia	Variable
Respiration	Periodic breathing	Apnea

**Figure 110-2** A standard checklist to determine eligibility for TH, which includes simplified examination findings to improve consistency among providers. IUGR, intrauterine growth restriction. (From Olsen SL, Dejonge M, Kline A, et al. Optimizing therapeutic hypothermia for neonatal encephalopathy. *Pediatrics*. 2013;131[2]:e591–e603.)

arteriosus (duct-dependent lesions), which occurs anywhere from the first 24 hours of life to the end of the first week of life. Symptoms from the remaining lesions appear later, as the pulmonary resistance continues to decline from 2 to 12 weeks. A normal physical examination and absence of murmur on the first day of life does not rule out congenital heart disease; approximately one-half of confirmed duct-dependent lesions are in infants whose initial physical examination was reported to be “normal.”

Although many congenital heart malformations are discovered by prenatal fetal ultrasounds that examine the 4-chamber view and major outflow tracts of the fetal heart, not all cases are picked up because of the technical demands of the skill of fetal echocardiography. Presence of a cardiac murmur often raises anxiety in the staff and parents because of the possibility of a congenital heart malformation. An audible murmur needs to be assessed: Does it have the characteristics of a clinically significant murmur, or is it an

Child in well-infant nursery at 24–48 hr of age or shortly before discharge if <24 hr of age

**Figure 110-3** The proposed pulse oximetry monitoring protocol based on results from the right hand (RH) and either foot (F). (From Kemper AR, Mahle WT, Martin GR, et al. Strategies for implementing screening for critical congenital heart disease. *Pediatrics*. 2011;128[5]:e1259–e1267.)

innocent one? Approximately one-half of the murmurs heard in the newborn period beyond the first day of life are innocent in nature. Innocent murmurs are short systolic in timing, have no diastolic component, have no ejection clicks, are less than grade 3/6 in intensity, and change intensity with posture change. Clinically significant murmurs, on the other hand, are louder (more than grade 3/6), are associated with palpable heave or thrill, may be holosystolic, may have a diastolic component, and may have ejection clicks. (See Chapter 101, The Newborn With a Heart Murmur or Cyanosis.)

An effort should be made to feel the femoral pulses on all newborns. If the pulses are difficult to feel, then blood pressure should be measured in both upper and lower limbs with an appropriate cuff size. Selecting an appropriate cuff size is important since an undersized cuff gives a higher reading and an oversized cuff underestimates the blood pressure. Cuff size is selected by measuring the circumference of the upper arm and following the manufacturer's recommendation. For example, Critikon neonatal blood pressure cuff size 1

is used for circumference of 3 to 6 cm, Size 2 for 4 to 8 cm, and Size 3 for 6 to 11 cm.

Presence of brachiofemoral delay in pulse or significant blood pressure difference in upper and lower limbs may point toward coarctation syndromes. A chest radiograph and electrocardiogram may be of some help. However, in the presence of a significant murmur, the referral NICU and the pediatric cardiology service should be contacted.

Pulse oximetry checking preductal saturation (right hand) and simultaneous post-ductal saturation (on either foot) beyond 24 hours or before discharge has been evaluated and recommended as routine screening for critical duct-dependent congenital heart malformations in newborn infants (Figure 110-3).

Sudden onset of poor feeding, cardiorespiratory compromise, metabolic acidosis, cyanosis, and no significant improvement in oxygenation while breathing 100% oxygen in a newborn beyond the first day of life should arouse suspicion of a duct-dependent cardiac malformation. Examples of duct-dependent lesions are hypoplastic left heart syndrome, left outflow tract

obstruction, coarctation of aorta, transposition of great vessels, tricuspid atresia, pulmonary stenosis, and atresia. Prostaglandin infusion may be initiated in consultation with the pediatric cardiology service as soon as possible. Other important differential diagnoses, such as sepsis or inborn error of metabolism, should be also kept in mind (Box 110-3).

### Abnormal Neurologic Signs

Neonatal seizure is the most common neurologic cause of referral to the NICU. Treatment should be based on reliable history from parents or from witness accounts by medical personnel. Seizures may need immediate attention for control, then clinical and diagnostic evaluation to find the cause. Neonatal seizures may be caused by perinatal hypoxia or ischemia, metabolic disturbances, intracranial hemorrhage or infarction, sepsis, or withdrawal syndrome, or they may be of the benign familial type. In the management of a clinical seizure, an important feature is to look for hypoglycemia before providing anticonvulsant therapy. Hypoglycemia should be assessed by a rapid blood glucose strip test. If hypoglycemia is present, the infant is treated with an intravenous glucose bolus first; if hypoglycemia is absent, then a loading dose of anticonvulsant is given. Other therapy will depend on the causative factor for the seizure. After the seizure is controlled, transfer should be initiated in consultation with the accepting NICU as further evaluation for the cause of seizure continues. (See Chapter 107, The Newborn With Neurologic Findings, and Chapter 327, Seizure Disorders)

Other neurologic causes for referral may include unexplained hypotonia (*floppy infant*), poor feeding, hypertonia, and exaggerated reflexes. The NICU team and pediatric neurology service should be consulted regarding whether the baby requires intensive care or whether the infant is feeding and stable enough to be followed up in the outpatient department.

### BOX 110-3 Well-Seeming Newborn With a Serious Underlying Disorder

- Neonatal sepsis (group B *Streptococcus* infection, *Escherichia coli* infection, herpes simplex virus infection) during incubation period
- Duct-dependent cardiovascular malformation (before ductus arteriosus starts closing)
- Gastrointestinal causes (small-bowel obstruction, malrotation, Hirschsprung disease) before feeding and abdominal distension
- Inborn errors of metabolism (before feeding and accumulation of offending metabolites)
- Congenital adrenal hyperplasia, particularly in boys (before any physiological stress)
- Congenital clotting disorders, particularly in boys (before circumcision)

### Congenital Anomalies

Life-threatening malformations that require early medical or surgical intervention, such as critical congenital heart defects, gastrointestinal atresias, gastroschisis, omphalocele, and diaphragmatic hernia, diagnosed by prenatal ultrasound, should preferably be delivered at a hospital with a NICU with the required subspecialty support. Presence of polyhydramnios or oligohydramnios on prenatal ultrasounds should alert the PCP to assess the affected infant for additional malformations. Polyhydramnios is associated with tracheoesophageal fistula and open neural tube defects, whereas oligohydramnios is associated with renal dysplasia, obstructive uropathy, and pulmonary hypoplasia. Occasionally, these infants are born in a community hospital without a prenatal diagnosis, or the mother experiences an unexpectedly rapid progression of labor before reaching a perinatal regional referral center. The PCP should contact the regional NICU team to optimize the pretransport stabilization.

### Dysmorphology

The most common dysmorphologies are trisomy 21, 18, and 13 phenotypes and their association with major organ system malformations. Other group associations include VACTERL (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb anomalies) and CHARGE (coloboma, heart disease, atresia choanae, retardation of growth or development, genitourinary tract anomalies, and ear anomalies), in which the presence of 1 feature leads to the discovery of another. Facial dysmorphic features (eg, frontal prominence, depressed nasal bridge, palpebral fissure slants, micrognathia, ear anomalies, facial clefts) may be present as isolated findings, but a combination of these findings along with others found by systemic examination should be discussed with the NICU or a genetic service (or both) for diagnosis and management. These infants may or may not require NICU care, depending on the presence or absence of any associated serious systemic malformations.

### Hematologic Problems

Acute hemorrhage, hypovolemia, and anemia may be life threatening and should be addressed promptly. Although volume resuscitation and blood transfusion are contemplated, the referral process to the NICU should be initiated. Early onset jaundice and pallor (within 24 hours of life) signifying hemolysis should be assessed promptly, and the infant should be referred after consultation with the accepting NICU. A ruddy-appearing baby might have polycythemia, which is defined as a venous hematocrit level of 65% or more. It is commonly associated with IDM, diabetes, small-for-gestational-age babies, Down syndrome, delayed clamping, and milking of the umbilical cord, and should be discussed with the NICU team. The issue of polycythemia caused by delayed cord clamping is an area of controversy, since a 2013 Cochrane database systematic review did not find a difference in the incidence of polycythemia between the early and late cord clamping groups in the 5 trials reporting this outcome. Thrombocytopenia caused

by maternally acquired antibodies may occasionally be severe enough to cause life-threatening bleeding in newborns, and referral should be decided with the NICU team and in consultation with pediatric hematology service.

### Hyperbilirubinemia

Jaundice within the first 24 hours after birth, particularly when associated with significant anemia, is a cause for concern and should be discussed with the regional referral hospital NICU team. Exaggerated physiological jaundice and breastfeeding jaundice are common causes of neonatal readmission to the hospital and can be managed at level I or level II facilities or on the general pediatric unit. (See Chapter 99, Neonatal Jaundice, for information on the management of this condition.)

### Inborn Errors of Metabolism

Inborn errors of metabolism (IEMs) are rare disorders when considered individually, but when considered together are found in 1 in 1,500 births by some estimates. Carbohydrate metabolism-related disorders (eg, galactosemia) will produce hypoglycemia, hepatic dysfunction, and acidosis. Aminoacidopathies (phenylketonuria, tyrosinemia, maple syrup disease) produce acidosis, encephalopathy, and hepatic dysfunction. Lipid metabolism disorders are errors with fatty acids and organic acidemias, medium-chain acyl-coenzyme A dehydrogenase deficiency, propionic academia, and primary lactic acidosis. Poor feeding, faster breathing, respiratory alkalosis, and encephalopathy in absence of significant metabolic acidosis may point towards urea cycle disorders. (See Chapter 105, Transient Metabolic Disturbances in the Newborn; and Chapter 106, Specific Congenital Metabolic Diseases.)

In a stable newborn, IEMs are diagnosed either as part of the state screening program or by way of prenatal or postnatal diagnostic workup in response to a positive family history of a genetic disorder. In either case, the PCP should contact the designated screening program or the genetics service for guidance. In an ill-appearing newborn in whom IEMs are suspected (sudden deterioration after 1–2 days or of feeding and unexplained severe acidosis or hypoglycemia), a few general screening tests may be performed to arrive at a diagnosis pending the results of the genetic testing (see Box 110-2).

### Endocrine Conditions

The most common endocrine derangement is neonatal hypoglycemia caused by increased fetal insulin in IDMs. Congenital hypothyroidism, generally discovered by newborn screening, is the next most common disorder. Congenital adrenal hyperplasia is usually detected in newborn girls because virilization leads to ambiguous genitalia; boys with the same condition are not discovered unless the state-mandated newborn screening tests detect increased levels of 17-hydroxyprogesterone. Transient hypoparathyroidism may produce hypocalcemia, but it may occasionally be the earliest clue to DiGeorge syndrome.

### In Utero Drug Exposure and Neonatal Abstinence Syndrome

In recent years there has been a surge in infants diagnosed with neonatal abstinence syndrome (NAS) resulting from increased abuse of prescription narcotic drugs by pregnant women. Abuse of other substances such as marijuana, cocaine, alcohol, and tobacco continues at previous rates, and more often multiple substance use occurs. Drug withdrawal manifests as jitteriness, increased muscle tone, inconsolable crying, and (rarely) seizures. Maternal history and results of drug screening tests are helpful. Infants exposed to in utero drugs are closely monitored, for instance using the Finnegan scoring system (primarily used for narcotic withdrawal), and appropriate interventions planned in consultation with the NICU attending, depending on the severity of the infant's symptoms. Infants with persistently high Finnegan scores (>8) with no response to nonpharmacological interventions like swaddling and minimal stimulating environment may need to be treated with medications such as morphine, methadone, or phenobarbital. During initiation of opiate therapy, infants require cardiorespiratory monitoring.

## ASSESSMENT OF WELL-APPEARING INFANTS

In a well-appearing infant, some clinical clues may be present that lead to the suspicion or diagnosis of a problem. This will assist the physician with the decision about the need for consultation or immediate referral of the infant to a NICU. Few situations occur in which the newborn seems apparently well only to show signs of a serious disorder later (Box 110-4; see

### BOX 110-4 Common Diagnostic Categories for an Ill-Seeming Newborn (Beyond 12 to 24 Hours After Normal Cardiopulmonary Transition at Birth)

- Respiratory distress: neonatal sepsis, pneumonia
- Critical congenital heart disease: duct-dependent cardiac lesion
- Common metabolic derangements: hypoglycemia, hypocalcemia
- Inborn errors of metabolism: unexplained, severe, persistent metabolic acidosis or hypoglycemia
- Neurologic problems: neonatal seizures, hypertonia, hypotonia, apnea
- Surgical conditions: Intestinal atresias, malrotation, volvulus, Hirschsprung disease, meconium ileus, ovarian cysts
- Endocrinological: disorders of sexual development (congenital adrenal hyperplasia)
- Hematologic problems: hyperbilirubinemia, anemia, polycythemia, severe alloimmune thrombocytopenia, congenital clotting disorders
- Genitourinary problems: renal dysplasia, hydronephrosis, hypertension

also Box 110-3). The 2 most common conditions that start as an apparently well newborn at birth who remains stable for a several hours to a few days before rapidly becoming symptomatic are neonatal sepsis and duct-dependent congenital heart disease.

After initial assessment, consideration of the conditions listed in Box 110-4 and based on the available resources at the primary care facility, a determination should be made after consultation with regional NICU team regarding the ongoing evaluation and treatment required by the infant at an appropriate level of care. The first consideration is immediate stabilization of the infant including the initiation of necessary diagnostic studies. Consultation with a neonatologist prior to neonatal transfer facilitates care coordination and provides an opportunity for discussion about interim evaluation, treatment and pretransport preparation. At the same time, PCPs should explain to the parents the reasons for the infant's transfer to a neonatal unit providing a higher level of care and the presumptive diagnosis and interim treatment plan. The PCP serves an integral role as medical liaison and support for the parents, assisting them in deciphering information about

their infant's condition, evaluation and treatment plans and expected outcome.

## SUMMARY

History of maternal gestation, prenatal maternal laboratory results, prenatal ultrasound results, and complete physical examination of an ill-appearing newborn are essential to arrive at a provisional diagnosis. An initial basic workup adds to the process of diagnosis and decision-making (see Box 110-2). Occasionally an apparently well-appearing newborn may have a serious underlying condition, although in most cases a warning sign will be present in the history, physical examination, or laboratory results that may provide a clue and reason to pursue further evaluation (Box 110-5). For the PCP, communication with the accepting NICU attending physician and with the baby's parents is crucial to this entire process.

## TOOLS FOR PRACTICE

### Medical Decision Support

- *Guidelines for Perinatal Care*, 7th ed (book), American College of Obstetricians and Gynecologists and American Academy of Pediatrics ([shop.aap.org](http://shop.aap.org))

### BOX 110-5 Warning Signs in an Apparently Well Term Baby

#### SEPSIS

- Increased difference of central to peripheral skin temperature of more than 1°C in a thermo-neutral environment
- Presence of skin or mucous membrane vesicles with inflamed base
- Complete blood cell count performed for risk factors shows neutropenia with left shift

#### CONGENITAL HEART DISEASE

- Positive pulse oximetry newborn screening
- Dysmorphic features: trisomy 21, 13, 18 syndromes, Turner syndrome
- Significant cardiac murmur
- Difference in femoral and brachial pulses or low blood pressure in lower limbs as compared with upper limbs
- Sudden onset of cardiorespiratory compromise in a previously well baby beyond the first day of life and no improvement in oxygenation while breathing 100% oxygen (hyperoxia test)

#### INBORN ERRORS OF METABOLISM

- Poor feeding after 1 or 2 days of initial normal feeding
- Unexplained metabolic acidosis, hypoglycemia
- Respiratory alkalosis, hyperammonemia
- Family history of inborn errors of metabolism or unexplained neonatal deaths

#### ENDOCRINE PROBLEMS

- Hypoglycemia: hyperinsulinism in large-for-date infants of diabetic mothers
- Hypoglycemia with microphallus: hypopituitarism, growth hormone deficiency

- Hypoglycemia, hypothermia, holoprosencephaly: panhypopituitarism
- Hypocalcemia with hyperphosphatemia: hypoparathyroidism
- Hyponatremia with hyperkalemia: ambiguous genitalia: congenital adrenal hyperplasia, adrenal insufficiency
- Hyperbilirubinemia, constipation, slow feeder: hypothyroidism
- Unexplained tachycardia with maternal history of Graves disease: hyperthyroidism

#### HEMATOLOGIC PROBLEMS

- Polycythemia: large ruddy-looking infant of diabetic mother or small for gestational age, chronically stressed baby caused by placental insufficiency, twin-twin transfusion
- Excessive bleeding from circumcision: clotting disorder, immune thrombocytopenia
- Jaundice within 24 hours with or without pallor: hemolytic disease

#### OTHER PROBLEMS

- Choking on attempts to feed or inability to pass orogastric or nasogastric tube, prenatal history of polyhydramnios: esophageal atresia or proximal bowel obstruction
- Bilious vomiting should raise concern about malrotation and midgut volvulus
- Inability to pass meconium after more than 24 hours with abdominal distension: mid or distal bowel obstruction, such as ileal atresia, left microcolon, cystic fibrosis, Hirschsprung disease
- Persisting jaundice with acholic stools: biliary atresia, cholestasis

low-birth-weight infants and term infants with known congenital anomalies are born in hospitals that are not designed to provide specialized care. In addition, some term infants will fail to transition or have unpredicted medical needs and require transport to a tertiary care center.

### STABILIZING INFANTS

Stabilizing a sick or premature infant before interfacility transport means first ensuring an adequate airway and then optimizing ventilation. The next most critical issue is evaluating and obtaining an effective blood circulating volume. After the airway, breathing, and circulation (ABCs) have been established, several other parameters that are crucial to maintaining neonatal stability should be addressed, including thermoregulation, glucose homeostasis, evaluation for sepsis and the efficacy of ongoing therapies, and family crisis support. Because dealing with a sick neonate is an infrequent occurrence for people working outside of neonatal intensive care units, the S.T.A.B.L.E. mnemonic was created by the developers of the S.T.A.B.L.E. course (www.stableprogram.org) to aid recall of these steps for managing the infant before transport. The mnemonic is as follows:

S = SUGAR and SAFE care  
 T = TEMPERATURE  
 A = AIRWAY  
 B = BLOOD PRESSURE  
 L = LABORATORY EVALUATION  
 E = EMOTIONAL SUPPORT

The remainder of this chapter will summarize the S.T.A.B.L.E. Program Learner Manual content and review each of these issues, in mnemonic order, as it applies to pretransport management.

### Sugar

Because the newborn infant is at risk for hypoglycemia, measuring serum glucose is imperative. Newborns have limited glycogen stores and since most glycogen is produced and stored during the third trimester, hypoglycemia is of particular importance for the premature infant. The sick newborn will have increased glucose utilization, and hyperinsulinemia may be present in the infant who is large for gestational age or the infant of a mother with diabetes. Other causes of increased glucose utilization include perinatal distress, respiratory distress, hypoxia, shock, hypothermia, sepsis, and cardiac disease. In conditions of normoxia, infants rely on aerobic metabolism, which is efficient in producing energy from glucose. However, during hypoxia, anaerobic metabolism occurs, which utilizes additional glucose to produce the same amount of energy. Inadequate glucose production occurs in premature infants and those who are small for gestational age. Some maternal medications potentiate infant hypoglycemia, including  $\beta$ -sympathomimetics,  $\beta$ -blockers, benzothiadiazine diuretics, and chlorpropamide. Infants with polycythemia or congenital hypopituitarism are also at risk for hypoglycemia.

## Chapter 111

# CARE OF THE SICK OR PREMATURE INFANT BEFORE TRANSPORT

Gina Marie Geis, MD; Karen S. Wood, MD

Organized neonatal transport programs emerged in the late 1970s when perinatal care shifted to regional centers. Regionalization of care promoted maternal-fetal transport and reduced the number of newborns requiring postnatal transport. In addition, regionalization resulted in improvements in perinatal mortality and neonatal morbidity as the percentage of very low-birth-weight infants delivered outside of tertiary care centers decreased. Sick or premature infants, however, continue to be delivered at institutions that are unable to provide for all of their medical needs. In some areas, organized regional perinatal care services have deteriorated. In all regions of the country, very

The goal range for serum glucose is 50 to 110 mg/dL (2.8–6.0 mmol/L). Hypoglycemia is traditionally defined as a serum glucose concentration of less than 40 mg/dL; however, to provide a buffer, 50 mg/dL is designated as the concentration at which to intervene for patients undergoing transport. In most instances, sick infants are not stable enough for oral feedings, and glucose administration will require placement of a peripheral intravenous catheter or umbilical venous catheter. The initial glucose infusion rate (GIR) should be 4 to 6 mg/kg/min; glucose can be delivered with 10% dextrose in water (D<sub>10</sub>W) at 80 mL/kg/day or in extremely low-birth-weight (<1,000 g) infants with D<sub>5</sub>W at 120 mL/kg/day. If the initial measured serum glucose concentration is less than 50 mg/dL, then a peripheral intravenous line should be inserted, with a GIR of 4 to 6 mg/kg/min and a 2 mL/kg D<sub>10</sub>W (200 mg/kg) glucose bolus given over 2 to 5 minutes. Higher-concentration glucose boluses are discouraged because of the rebound hypoglycemia that can follow. A repeat serum glucose measurement should be performed 15 to 30 minutes after the bolus. If subsequent glucose measurements continue to be less than 50 mg/dL, the physician must first ensure that the intravenous line is functioning and that a GIR of 4 to 6 mg/kg/min is being delivered, and then an additional 2 mL/kg D<sub>10</sub>W bolus should be given intravenously. As needed, 2 glucose boluses may be given before increasing the GIR, which should be done in increments of 2 mg/kg/min. The physician should continue to repeat the serum glucose measurements until 2 successive measurements are greater than 50 mg/dL. Infants with hyperinsulinemia may need a GIR twice the initial starting rate and may require an increased fluid rate or a central line to achieve this goal. The steps for managing serum glucose are outlined in Box 111-1.

### Temperature

A neutral thermal environment has an important effect on the well-being of a newborn. Although the

seminal work by Silverman demonstrated increased survival in a neutral thermal environment for premature infants only, in practice, this principle is used for all newborns. Oxygen consumption increases at temperatures above and below the neutral thermal range. Hypothermia is a significant predictor of neonatal morbidity and mortality, particularly in the transport literature. Studies have demonstrated that head cooling or whole-body hypothermia may have advantages for neurologic outcome in a subset of neonates who have suffered a hypoxic insult at birth. However, for the general neonatal population, normothermia is the goal. The normal core temperature range for an infant is 97.7°F to 99.5°F (36.5°C–37.5°C). Every effort should be made to prevent heat loss in the neonate because rewarming an infant who has become hypothermic can be difficult.

All infants are at risk for hypothermia. Groups at higher risk include preterm infants, particularly those weighing less than 1,500 g; infants who are small for gestational age; infants who are hypoxic or those who require a prolonged resuscitation; acutely ill infants with infectious, cardiac, endocrine, neurologic, or surgical issues (abdominal wall and neural tube defects); infants who are sedated or paralyzed; and infants with hypoglycemia. During the transition to extrauterine life, an infant can lose heat at rates up to 1.0°C/min. The recommended delivery room temperature range, therefore, is 77°F to 82.4°F (25°C–28°C).

Heat can be lost by a variety of mechanisms; however, by the law of thermodynamics, heat always flows from warm to cold. Conductive heat loss occurs when the infant comes in contact with a cooler object such as a mattress, scale, stethoscope, blanket, or care provider. Warming objects (not to exceed 40°C) that the infant contacts and providing insulators, such as hats, are good mechanisms to avoid conductive heat loss. Convective heat loss occurs from the skin surface to the surrounding air and is increased when the environmental air temperature is colder or when the air currents are higher. Careful attention to the environmental temperature, including use of a prewarmed isolette or nonobstruction of the overhead heat source on a radiant warmer, and avoiding drafts, including cold oxygen currents, can help eliminate convective heat loss. Infants weighing less than 1,500 g should be covered with polyethylene plastic from neck to feet to reduce convective heat loss until a humidified environment can be provided. Radiant heat loss occurs between solid surfaces not in contact with each other. The heat sink is usually a cold wall or window, although a cold radiant warmer or isolette can have the same effect. The infant should not be located close to a cold solid object, and thermal shades and covers should be used. Finally, heat can be lost through the mechanism of evaporation, which is a particular concern in the delivery room. Evaporative losses occur when moisture on the skin surface or in the respiratory tract is converted into vapor, with a concurrent cooling effect. This type of heat loss can be minimized by drying the infant after delivery or bathing. No infant should be bathed until a normal core temperature has been established and the infant is otherwise stable. Oxygen should

#### BOX 111-1 Serum Glucose Management

- Step 1: Make sure the neonate receives nothing by mouth.
- Step 2: Start IV glucose infusion at 4 to 6 mg/kg/min
- Step 3: Check serum glucose (Step 3 may precede Step 2)
- Step 4: If serum glucose is <50 mg/dL then:
  - a. Check IV infusion rate
  - b. Administer a bolus of 2 mL/kg D<sub>10</sub>W
  - c. Recheck serum glucose in 15 to 30 minutes
  - d. May proceed through Step 4 twice
- Step 5: If serum glucose is <50 mg/dL after 2 boluses, then:
  - a. Increase glucose infusion by 2 mg/kg/min
  - b. Recheck serum glucose in 15 to 30 minutes
  - c. Repeat Step 5 as needed
- Step 6: If serum glucose is >50 mg/dL, then recheck serum glucose in 30 to 60 minutes
- Step 7: If serum glucose is >50 mg/dL on 2 serial checks, then space glucose measurements to 1 to 3 hours

D<sub>10</sub>W, 10% dextrose in water; IV, intravenous.

be heated and humidified as soon as possible. Polyethylene plastic wrap covering the infant can also reduce evaporative heat loss.

Term infants have adaptive mechanisms in response to cold stress, including peripheral vasoconstriction, increased muscle activity and flexion, and brown adipose metabolism. These mechanisms require oxygen and glucose. Peripheral vasoconstriction prevents blood flow to and heat loss from the skin surface. Infants cannot shiver; however, muscle activity generates some heat, and flexion conserves the surface area from which heat can be lost. Brown adipose is metabolized in response to cold stress with norepinephrine release, creating nonshivering thermogenesis. Brown adipose is accumulated throughout gestation, predominantly during the third trimester, and has a unique capability for extraordinary energy production and subsequent heat production. Pulmonary vasoconstriction occurs in addition to peripheral vasoconstriction in response to norepinephrine release and can lead to persistent pulmonary hypertension. The cascade of problems that occur with hypothermia is demonstrated in Figure 111-1.

In the event of heat loss, rewarming must occur, though rapidly rewarming the patient can result in vasodilation and hypotension. Unfortunately, no studies exist to define rewarming rates that are too fast or

too slow. If the infant is rewarming in an isolette, then the air temperature should be set to 1.0°C to 1.5°C above the infant's core temperature; after equilibration, the air temperature should be increased by an additional 1.0°C to 1.5°C until the infant's core temperature is within the normal range. If the infant is being rewarmed with a radiant warmer, then overly aggressive rewarming should be avoided. The servo control should not be set to greater than or equal to 36.5°C unless the infant's temperature is within 1.5°C of this value. The neonate's response to rewarming should be monitored, and the speed of rewarming, depending on tolerance, should be adjusted.

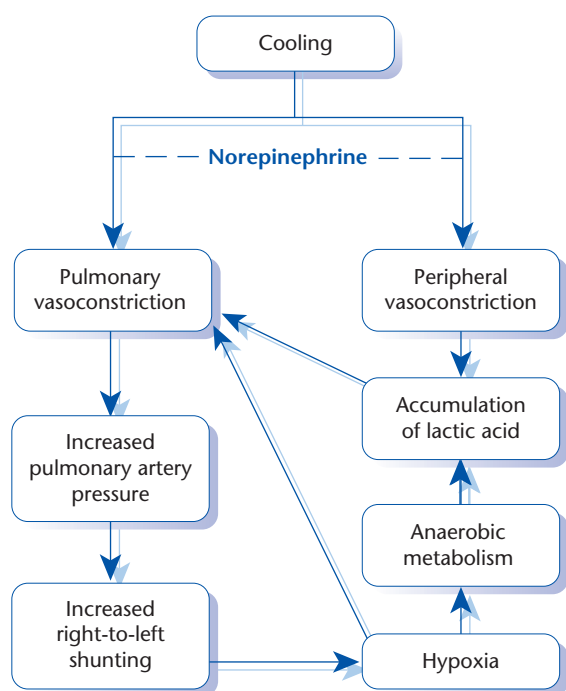

### Airway

Stabilizing the airway usually represents the most critical management dilemma in a pretransport newborn. The most common diagnosis requiring transport to a neonatal intensive care unit is respiratory distress. Respiratory failure can occur quickly but may be thwarted by early respiratory support, including correct airway positioning, supplemental oxygen therapy via hood or nasal cannula, continuous positive airway pressure (CPAP) via high-flow nasal cannula or CPAP device, or assisted ventilation through an endotracheal tube. The amount of support needed may change during the pretransport period, necessitating constant reevaluation of the patient's respiratory requirements. If adequate ventilation for the infant is not achieved, then other management strategies, including medications, will not be effective.

The normal respiratory rate for a newborn is 40 to 60 breaths per minute. Respiratory distress may manifest as apnea, poor air entry on auscultation, cyanosis, or increased work of breathing, such as tachypnea, retractions, grunting, or nasal flaring. The newborn can endure hypoxia for only a brief period, during which the infant relies on anaerobic metabolism, metabolizes large amounts of glucose, and produces significant quantities of lactic acid. If hypoxia continues, profound metabolic acidosis causes cellular dysfunction and cell death with organ injury. A postductal saturation measurement provides an estimation of oxygenation and is useful for continuous monitoring; however, an arterial blood gas test is the gold standard for assessing oxygenation, ventilation, and acid-base balance and can guide further management. A low partial pressure of carbon dioxide in arterial blood with tachypnea typically represents a nonpulmonary cause of respiratory distress, such as congenital heart disease, metabolic acidosis, or central nervous system dysfunction. A high partial pressure of carbon dioxide with tachypnea typically represents a pulmonary cause, such as pneumonia, meconium or amniotic fluid aspiration, pneumothorax, respiratory distress syndrome, airway obstruction, or pulmonary hypoplastic syndromes such as chest mass or congenital diaphragmatic hernia. A chest radiograph should be obtained to help diagnose the cause of respiratory distress and define the extent of disease. (See Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn.)

Rarely does a term newborn require CPAP; therefore using the oxygen hood is usually the best technique to

### Cardiovascular Response to Cold Stress in the Critically Ill Newborn

**Figure 111-1** Cardiovascular response to hypothermia. (From Baumgart S. *Incubation of the human newborn infant*. In: Pomerance JJ, Richardson CJ, eds. *Neonatology for the Clinician*. Norwalk, CT: Appleton & Lange, 1993. Copyright McGraw-Hill Education. Used with permission.)

supply oxygen to nonventilated newborns. Unlike the nasal cannula, the hood allows measuring the amount of oxygen being supplied to the nares. In term infants, the use of high oxygen concentrations (fraction of inspired oxygen = 1.0) in the time frame for stabilization is permissible. Using a nasal cannula to provide oxygen therapy is common practice; however, this method also provides unnecessary CPAP, which increases the risk for air leak and is therefore not the best choice for term patients. If an insufficient amount of oxygen is being delivered via the hood or the patient's respiratory status is deteriorating, then the infant should be intubated and placed on assisted ventilation. The endotracheal tube size and placement depth are dictated by the infant's weight (Table 111-1). The initial ventilator settings should consider the patient's gestational age, weight, and disease process (Table 111-2).

In contrast, in preterm infants, judicious use of oxygen therapy must occur because of the known retinal and pulmonary toxicities of oxygen. Premature infants often need CPAP but little supplemental oxygen; therefore, the best initial device for them is CPAP or a nasal cannula with a flow meter and blender to deliver the minimal necessary oxygen concentration.

**Table 111-1** Endotracheal Tube Size and Placement Depth

WEIGHT (G)	TUBE SIZE (MM)	TUBE INSERTION DEPTH (CM)
<1,000	2.5	6.5–7.0
1,000–2,000	3.0	7–8
2,000–3,000	3.5	8–9
>3,000	3.5–4.0	>9

Adapted from Kattwinkel J. *Textbook of Neonatal Resuscitation*. 5th ed. Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association; 2006.

Given that CPAP devices are not universally available, increasing flow rates with the nasal cannula can create CPAP. A flow rate not to exceed 2 L/min should be sufficient for newborn premature infants. For infants requiring more support, intubation and assisted ventilation should be provided (see Table 111-1 and Table 111-2). (See Chapter 109, Assessment and Stabilization at Delivery.)

Respiratory distress can result from parenchymal lung disease but can also be caused by airway obstruction. Obstruction can occur at any point in the airway: nose, mouth, jaw, larynx, trachea, or bronchi. Upper airway obstruction can produce the aforementioned signs of respiratory distress, as well as stridor. The character of the stridor can suggest the level of obstruction. (See Chapter 197, Stridor.) The diagnosis of choanal atresia can be excluded by the ability to pass a catheter through each nare. Patients with choanal atresia often need only an oral airway but may need intubation to bypass the obstruction. Nasal cannula and CPAP devices are ineffective in choanal atresia. Infants with Pierre Robin sequence have micrognathia, cleft palate, and airway obstruction from the posterior position of the tongue. These infants often improve with prone positioning, allowing the tongue to fall forward with gravity. An oral airway or a laryngeal mask airway, if available, may be effective. If these mechanisms fail, then an endotracheal tube can be passed through the nares to the pharynx and be used to supply humidified oxygen or CPAP. If all these mechanisms are ineffective, then endotracheal intubation should be performed. However, endotracheal intubation can be technically difficult because of the micrognathia.

Persistent pulmonary hypertension (PPHN) can occur with sustained elevation of pulmonary vascular resistance after birth and persistence of fetal circulation. Given that blood follows the path of least resistance, it is shunted from right to left, away from the lungs, through the ductus arteriosus or foramen ovale, resulting in hypoxemia. Idiopathic PPHN can occur, and PPHN can accompany hypothermia, sepsis, congenital

**Table 111-2** Suggestions for Initial Ventilator Support for Infants of Varying Weights

SETTINGS	VLBW (<1.5 KG)	LBW (1.5–2.5 KG)	TERM (>2.5 KG)
Rate (per minute)	30–45	20–40	20–40
Inspiratory time (in seconds)	0.30–0.35	0.30–0.35	0.35–0.40
Positive inspiratory pressure (PIP) (cm H <sub>2</sub> O)	16–22	18–24	20–28
Positive end expiratory pressure (PEEP) (cm H <sub>2</sub> O)	4–7	4–7	4–7

LBW, low birth weight; VLBW, very low birth weight.

Notes:

1. PEEP

- The amount of PEEP selected will be based on the infant's disease process and goals of therapy.
- A PEEP of 4 may be insufficient and may result in collapse of the alveoli.
- Excessive PEEP for the disease process and clinical situation may impair ventilation, lung perfusion, or venous return (return of deoxygenated blood to the right side of the heart).

- The amount of pressure required (PIP) will also vary depending on the infant's size, disease state, and response to ventilation. Start with pressure in the lower end of the range and adjust up or down as needed based on the infant's response to treatment, chest x-ray, blood gas, and physical examination.
- An inspiratory time greater than 0.5 seconds may result in air trapping and increase the risk for barotrauma and injury to the lung tissue.
- A chest x-ray and blood gas may be helpful to assess response to changes.

From Karlsen KA. *The S.T.A.B.L.E. Program. Post-resuscitation/Pre-transport Stabilization Care of Sick Infants. Guidelines for Neonatal Healthcare Providers: Learner Manual*. 6th ed. Salt Lake City, UT: S.T.A.B.L.E. Program; 2006. Used by permission.

heart disease, or birth depression. However, most cases of PPHN occur with a parenchymal lung disorder such as meconium aspiration, pulmonary hypoplasia, pneumonia, or respiratory distress syndrome. With prompt recognition and early management of PPHN, infants typically need far less support than those with delayed diagnosis.

PPHN should be considered in any infant with respiratory distress. Infants with PPHN will have tachypnea, cyanosis, and lability in oxygen saturations. The presence of PPHN is suggested by a preductal-to-postductal oxygen saturation difference greater than or equal to 10%. Some infants with PPHN will shunt only at the atrial level and will not display this preductal-to-postductal saturation difference but will have lower than normal oxygen saturations. The chest radiograph in infants with PPHN may demonstrate parenchymal lung disease or decreased vascular markings, as in idiopathic PPHN, as well as a heart size that is normal or slightly enlarged. PPHN is also suggested by a low partial pressure of oxygen on an arterial blood gas sample; however, congenital heart disease needs to be ruled out in these patients. Providing adequate oxygen and eliminating acidosis may significantly improve the partial pressure of oxygen in patients with PPHN but not in patients with congenital heart disease. Comparison of an arterial blood gas test in room air and a second arterial blood gas test after 30 minutes of 100% oxygen (fraction of inspired oxygen = 1.0) exposure is known as the hyperoxic challenge test. An improvement in the partial pressure of oxygen to 100 mm Hg or higher with the hyperoxic challenge test is suggestive of a pulmonary process over a structural cardiac disorder. Echocardiography is the gold standard for diagnosing congenital heart disease but is often unavailable in the pretransport setting. Prostaglandin E<sub>1</sub> should be considered for any infant not responding to conventional ventilatory strategies until the structural cardiac anatomy can be defined. Therapy for PPHN includes adequate ventilation and oxygenation (may require intubation), correction of acidosis or mild alkalosis, provision of sedation and analgesia, maintenance of adequate cardiac output via volume and inotropic support, elimination of hypothermia, correction of polycythemia but maintenance of a normal hematocrit, and correction of metabolic abnormalities, including hypoglycemia and hypocalcemia. After all of these therapies have been optimized, inhaled nitric oxide can be considered; extracorporeal membrane oxygenation should be contemplated only as a last therapeutic option.

Pneumothorax occurs often in neonates. In fact, based on radiographic surveys, spontaneous pneumothoraces occur in 1% to 2% of all live births and are a consequence of the high negative intrapleural pressures (40–100 cm of water) produced with initial respirations in a newborn. Despite a high frequency of occurrence, most pneumothoraces are asymptomatic. Parenchymal lung disease, resuscitation at birth with positive pressure ventilation, or assisted ventilation in the neonatal period increases the risk for a symptomatic pneumothorax. Surfactant replacement and ventilation using lower peak airway pressures (gentle ventilation) have decreased the

incidence of air leaks, particularly in the preterm population.

Pneumothorax can be the primary cause of respiratory distress, or it can arise as a complication of lung disease. Air accumulating in the pleural space can compress the lung, affect ventilation, and, in severe cases, restrict cardiac output. A pneumothorax should be suspected in any infant who undergoes a rapid deterioration of respiratory status, especially if an associated cardiovascular collapse occurs. However, smaller air leaks can produce an insidious change in vital signs. A pneumothorax can usually be diagnosed by an anterior-posterior view chest radiograph, although a lateral view is occasionally needed. With an unstable infant, as seen with a tension pneumothorax, there may not be time to wait for the radiograph, and in these cases transillumination of the chest can be used to diagnose the pneumothorax. Transillumination indicates a pneumothorax if the fiber-optic light on the chest wall demonstrates a degree of lucency in excess of the usual 2- to 3-cm halo around the probe tip. A completely collapsed lung can demonstrate a false-negative transillumination. The room should be dark, and the transilluminator light source needs to be bright. False-positive transillumination can occur with chest wall edema, subcutaneous air, pneumomediastinum, and severe pulmonary interstitial emphysema.

Asymptomatic infants with a small pneumothorax require only close observation. Infants with respiratory distress may benefit from oxygen therapy best delivered without positive pressure via an oxygen hood. Unstable infants will require evacuation of the pneumothorax with needle decompression or thoracostomy tube placement. The presence of parenchymal lung disease or ongoing positive pressure ventilation substantially increases the need for evacuation. Needle decompression is performed in the second intercostal space in the midclavicular line. The thoracostomy tube should be inserted in the fourth or fifth intercostal space at the midpoint of the anterior axillary to mid-axillary line for an anterior tube placement. If size 10 or 12 French thoracostomy tubes are not available and continuous evacuation of air leak is necessary, then a 23-gauge butterfly needle can be placed, as in needle decompression, and the end of the tubing submerged in sterile water for temporary drainage.

### Blood Pressure

Hypotension results in inadequate oxygen delivery to the tissues. In newborns, hypotension occurs secondary to hypovolemia, heart failure, sepsis, or a combination of these conditions. In the extremely low-birth-weight infant, adrenal insufficiency may be an isolated cause for hypotension. Delaying treatment of shock can lead to multisystem organ failure and death; therefore early identification is essential.

The normal range for blood pressure varies by gestational age, and the exact normal range remains controversial. It is a commonly used convention that the mean blood pressure should approximate gestational age. Given that low blood pressure is a late finding in cardiac collapse, early signs of compromise must be identified. The physical examination findings of hypotension include weak peripheral pulses,

cyanosis, poor perfusion (represented as a capillary refill time  $>3$  seconds), pallor, and mottled and cool skin. Cardiac output is a product of stroke volume and heart rate. Although older patients increase cardiac output by increasing stroke volume, the infant has a poorly compliant myocardium and therefore relies on increased heart rate to increase cardiac output. Infants with hypotension will initially demonstrate tachycardia but progress to bradycardia before arrest. Infants in shock will also demonstrate respiratory distress with increased work of breathing, tachypnea, apnea, and finally gasping as a sign of impending cardiac arrest. Urine output, particularly after the first 24 hours of life, can be used to approximate cardiac output.

The most common cause of hypotension is hypovolemia resulting from hemorrhage occurring during the intrapartum or postpartum period. However, sepsis, dehydration, pneumothorax, or pneumoperitoneum can impair ventricular filling and lead to hypovolemic hypotension. A second cause of hypotension is heart failure that results from asphyxia, hypoxia, metabolic acidosis, infection, severe metabolic and electrolyte disturbances, arrhythmias, or congenital heart disease. The final category of hypotension is that caused by sepsis, which typically produces distributive shock with the loss of vascular tone and accompanying capillary leak. Infants can have hypotension from any or a combination of these different causes, and each will have its own management plan.

Treatment for the infant in hypovolemic shock relies on volume resuscitation. Initially, volume expansion should use lactated Ringer solution or normal saline at 10 mL/kg. If the patient is anemic, then ideally, cross-matched packed red cells should be given. Infants should be reassessed for further volume replacement. Cardiogenic failure is best treated with inotropic agents such as dopamine, dobutamine, or epinephrine. The starting dose for dopamine or dobutamine is 5 mcg/kg/min and should be titrated to the desired mean blood pressure or effect. In septic shock, capillary leak and the ongoing third-space losses will require volume replacement, and the cardiac effects will require inotropic support. Requiring large amounts of volume replacement is not uncommon for infants in septic shock. Patients with cardiogenic and septic hypotension can have significant metabolic acidosis; however, the use of sodium bicarbonate is controversial and reserved for term infants who are well ventilated and have a pH of less than 7.15. The most effective therapy for these infants is to identify and treat the cause of the metabolic acidosis. Also important in the face of hypotension is maintaining adequate glucose, calcium, sodium, and potassium for optimal cardiac function. (See also Chapter 373, Shock.)

## LABORATORY EVALUATION

Before transport, the 4 laboratory specimens that are helpful to obtain are:

- Blood glucose
- Blood gas
- Complete blood count
- Blood culture

## Blood Glucose

The reader is referred to the Sugar section earlier in this chapter.

## Blood Gas

A blood gas test is essential because most patients referred to higher-level centers will have respiratory symptoms, and the acid-base balance gives valuable diagnostic information. An arterial blood gas test is preferred if the distinction between a cardiac disorder and a respiratory disease remains in question; however, a capillary blood gas level is often easier to obtain and is acceptable to assess pH and ventilation. The blood gas analysis helps define the infant's status and can be communicated to the consultant at the referral center to determine further management and urgency of transport.

The reader is referred to the Airway section earlier in this chapter.

## Blood Count and Blood Culture

The complete blood count and the blood culture are the essential components of an initial sepsis evaluation in a neonate. Because all neonates are immunodeficient, and because failure to treat a septic infant can be fatal, performing a sepsis evaluation in a symptomatic infant is critically important. The risk factors for neonatal sepsis include premature rupture of membranes, rupture of membranes more than 18 hours, maternal fever, recent maternal infection or illness, maternal urinary tract infection, maternal chorioamnionitis, maternal group B streptococcal colonization, fetal distress, perinatal asphyxia, low birth weight, male gender, and intrapartum or postpartum instrumentation. Clinical signs of sepsis can be subtle or dramatic and include respiratory distress, temperature instability, abnormal skin perfusion, abnormal heart rate, abnormal blood pressure, feeding disturbance, and neurologic dysfunction. Given the wide spectrum of presentation for sepsis and the fact that considerable overlap exists with other diagnoses, it is imperative to obtain blood work and initiate antibiotic therapy until infection is ruled out.

Causative agents for neonatal sepsis are not always bacterial. However, bacterial infections are more common in the neonate than in patients at any other stage in life, and bacteria are the organisms to which therapy should be targeted in the pretransport period. The most common infecting organisms include group B *Streptococcus*, *Escherichia coli*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, and, less commonly, *Enterococcus*, *Klebsiella pneumoniae*, *Streptococcus pneumoniae*, *Listeria monocytogenes*, *Pseudomonas aeruginosa*, *Serratia marcescens*, *Enterobacter*, *Neisseria meningitidis*, and group A *Streptococcus*. A blood culture, preferably 1 mL in volume, collected from a carefully prepped site can identify the infectious agent. Obtaining the blood culture should precede antibiotic administration; however, antibiotic delivery should not be delayed if a culture cannot be obtained.

The complete blood count and differential may suggest sepsis if it reveals neutropenia, neutrophilia, immature neutrophils, thrombocytopenia, or

thrombophilia. Neutrophils are the critical component of defense against bacterial infections, and elevation of neutrophil counts can signal sepsis, although a diminished neutrophil count is much more ominous for neonatal sepsis. When neutrophils are depleted, the bone marrow produces more immature neutrophils. The diagnosis of sepsis should be entertained with neutropenia, especially an absolute neutrophil count below 1,800/mcL, or an immature to total neutrophil ratio above 0.15 in the first 24 hours of postnatal life. Thrombocytopenia may indicate sepsis. The normal range for the platelet count of a term infant is 310,000 ( $\pm$ 68,000)/mcL. Thrombocytopenia is defined as a platelet count less than 150,000/mcL. For term infants, the risk of bleeding is low until platelet counts drop below 30,000/mcL, and therefore platelet transfusions are rarely necessary in the pretransport period. An essential point to note is that the complete blood count is not diagnostic for sepsis. An infant with sepsis can have normal values in the complete blood count, and an infant without sepsis can have an abnormal complete blood count.

The suggested therapy for presumed early-onset neonatal sepsis consists of ampicillin and gentamicin. The ampicillin dose is 100 mg/kg/dose every 12 hours intravenously. This higher dose is used because meningitis is not easily excluded with an initial neonatal sepsis evaluation. Gentamicin should be dosed in accordance with the NeoFax guidelines, with dose ranges from 4 to 5 mg/kg/dose every 24 to 48 hours depending on postmenstrual and postnatal age. According to current NeoFax guidelines, neonates who are  $\leq$ 29 weeks postmenstrual age and between 0 and 7 postnatal days of age should be administered gentamicin 5 mg/kg/dose IV every 48 hours. For neonates who are 30-34 weeks postmenstrual age and between 0 and 7 postnatal days of age, gentamicin dosing should be 4.5 mg/kg/dose IV every 36 hours. For neonates  $\geq$ 35 weeks postmenstrual age and for all postnatal days of life, gentamicin dosing should be 4 mg/kg/dose IV every 24 hours. The antibiotic regimen is continued until sepsis is satisfactorily ruled out; this typically requires monitoring of the blood culture for a minimum of 48 hours.

Early-onset group B streptococcal (GBS) infection can occur in the first week of life as sepsis, pneumonia, meningitis, or any combination. The incidence of this infection has decreased in recent years with the implementation of maternal carrier screening and peripartum antibiotics. Neonates who demonstrate signs of sepsis at birth should have a blood culture obtained, and should be started on antibiotics. Given that premature infants have an increased risk of early-onset GBS disease compared with term infants, and because distinguishing GBS disease from respiratory distress syndrome is often difficult, these preterm infants more frequently deserve an initial sepsis evaluation.

## EMOTIONAL SUPPORT

An ill newborn requiring transfer to another hospital represents a significant and unexpected crisis for most parents. Feedback from parent support groups reveals

that for infants being transferred, while the needs of the neonate are being met, the needs of the parents often are not. Parents should be informed of the assessment and plan for their infant. This information often needs to be repeated because families may be in shock and not fully understand the information that is provided. In addition, maternal health status and peripartum medications received can affect a mother's ability to understand her infant's medical condition.

Families receiving catastrophic news undergo the stages of grief as outlined by Elisabeth Kübler-Ross in her book *On Death and Dying*: shock, denial, anger, bargaining, depression, testing, and acceptance. During the pretransport period, it is typical for families to be in the earliest stages, expressing shock and denial, finding it incomprehensible that what was supposed to be a happy, uncomplicated event has gone awry. However, individual family members transition through these stages at different speeds and sometimes in different orders. Consequently, the caretaking team needs to be capable of managing families in all stages of grief. A designated hospital staff member must be responsible for communicating directly with the family during the stabilization period and after departure of the infant. The parents should be encouraged to write questions down for the physician or transport team because forgetting questions is common when under stress.

The caretakers communicating with the family should identify the infant as personally as possible. Family members should be encouraged to touch their infant, take pictures, and when appropriate, obtain mementos such as footprints or a lock of hair. Any additional sources of support such as family members, friends, or members of the clergy should be identified and contacted. The assigned communicator should accompany the transport team to the mother's room and stay to hear the discussion with the family because questions will inevitably arise once the team leaves. Once the transport team departs with the neonate, the caretaking team should switch its focus from taking care of the infant to taking care of the parents. A helpful measure is to review with the family the information communicated by the transport team, such as the new caretakers for the infant, the plan of care at the receiving hospital, and directions to the receiving hospital. Also important is assessing the parents' response and coping mechanisms when the infant departs. Inquiring into the mother's plan to breastfeed and obtaining a breast pump (many insurance plans will provide mothers with a hospital-grade electric breast pump if the infant is hospitalized and unable to nurse) and encouraging her to proceed with breast milk expression can be useful. Offering to help the parents make subsequent contact with the center caring for their infant is appropriate.

Few parents anticipate that their term newborn will not be healthy, and families having preterm infants are ill prepared for birth, much less for coping with an infant requiring critical care. Providing families with information, an opportunity to talk and grieve, support in their time of crisis, and close personal follow-up is an essential and often overlooked portion of providing care in the pretransport stabilization period.

The authors wish to thank Diane Warner and Kristine Karlsen, whose contributions were instrumental in preparing the initial version of this manuscript.

## Chapter 112

# CONTINUING CARE OF THE INFANT AFTER TRANSFER FROM NEONATAL INTENSIVE CARE

Deborah E. Campbell, MD

The scope of continuing or convalescent hospital care for the infant returned to a community hospital after neonatal intensive care (*back transfer*) varies based on the child's underlying medical problems and ongoing health needs. In addition to maintaining bed availability within regional or tertiary neonatal intensive care units (NICUs), an important aspect of care for the infant who is back transferred is to foster the parent-infant relationship and bonding. It is well known that the separation imposed by the need to transport a sick newborn, often long distances, for tertiary care creates tremendous hardships for families. Parents' active involvement in their child's in-hospital care, preparation for their baby's discharge home, and post-hospital care are critical to facilitating the transition from hospital to home. Back transport to a community special care nursery (level II) or well newborn nursery (level I) can facilitate linking the child and family with follow-up systems within the community in which the child resides. (Table 112-1 describes levels of neonatal care.) Costs for care are often less than at the regional perinatal center or community level III NICU; a successful transfer also promotes a reciprocal relationship between the community hospital and tertiary center that fosters communication and collaboration.

The hospital to which the infant is returned ("back transported") and the timing of the return transfer depend on the individual patient's health care needs and the capability of the receiving hospital. Under certain circumstances within some integrated health care delivery networks or regionalized perinatal care networks, an infant may be transferred to a facility with a lower level of care that was not the birth hospital to complete treatment and preparation for discharge home. Infants transferred to level II units include extremely low-birth-weight infants needing convalescent care, infants with chronic lung disease of infancy, infants with feeding problems, infants receiving antibiotic therapy, and infants with nonacute surgical, neurosurgical, and subspecialty medical issues. Some infants may have stable or regressing retinopathy of prematurity (ROP) or apnea of prematurity (AOP) requiring infrequent or no stimulation. Infants

**Table 112-1** Definitions, Capabilities, and Provider Types: Neonatal Levels of Care

LEVEL OF CARE	CAPABILITIES	PROVIDER TYPES <sup>a</sup>
Level I Well newborn nursery	<ul style="list-style-type: none"> <li>• Provide neonatal resuscitation at every delivery</li> <li>• Evaluate and provide postnatal care to stable term newborn infants</li> <li>• Stabilize and provide care for infants born at 35 to 37 weeks' gestation who remain physiologically stable</li> <li>• Stabilize newborn infants who are ill and those born at less than 35 weeks' gestation until transfer to a higher level of care</li> </ul>	Pediatricians, family physicians, physician assistants, pediatric or family nurse practitioners, and other advanced practice registered nurses
Level II Special care nursery	Level I capabilities plus: <ul style="list-style-type: none"> <li>• Provide care for infants born at 32 or more weeks' gestation and weighing 1,500 g or more who have physiologic immaturity or who are moderately ill with problems that are expected to resolve rapidly and are not anticipated to need subspecialty services on an urgent basis</li> <li>• Provide care for infants convalescing after intensive care</li> <li>• Provide mechanical ventilation for brief duration (&lt;24 hours) or continuous positive airway pressure or both</li> <li>• Stabilize infants born before 32 weeks' gestation and weighing less than 1,500 g until transfer to a neonatal intensive care facility</li> </ul>	Level I health care providers plus: Pediatric hospitalists, neonatologists, and neonatal nurse practitioners
Level III NICU	Level II capabilities plus: <ul style="list-style-type: none"> <li>• Provide sustained life support</li> <li>• Provide comprehensive care for infants born at less than 32 weeks' gestation and weighing less than 1,500 g and infants born at all gestational ages and birth weights with critical illness</li> <li>• Provide prompt and readily available access to a full range of pediatric medical subspecialists, pediatric surgical specialists, pediatric anesthesiologists, and pediatric ophthalmologists</li> <li>• Provide a full range of respiratory support that may include conventional or high-frequency ventilation and inhaled nitric oxide</li> <li>• Perform advanced imaging with interpretation on an urgent basis, including computed tomography, MRI, and echocardiography</li> </ul>	Level II health care providers plus: Pediatric medical subspecialists, <sup>b</sup> pediatric anesthesiologists, <sup>b</sup> pediatric surgeons, and pediatric ophthalmologists <sup>b</sup>
Level IV Regional NICU	Level III capabilities plus: <ul style="list-style-type: none"> <li>• Located within an institution with the capability to provide surgical repair of complex congenital or acquired conditions</li> <li>• Maintain a full range of pediatric medical subspecialists, pediatric surgical subspecialists, and pediatric anesthesiologists at the site</li> <li>• Facilitate transport and provide outreach education</li> </ul>	Level III health care providers plus: Pediatric surgical subspecialists

<sup>a</sup>Includes all providers with relevant experience, training, and demonstrated competence<sup>b</sup>At the site or at a closely related institution by prearranged consultation agreementFrom American Academy of Pediatrics Committee on Fetus and Newborn. with life-limiting conditions may be transferred to a community hospital nearer to their homes and families for hospice (comfort) care. Box 112-1 provides a summary of the benefits of and requirements for return transfer.

The continuing care needs of the infant who is transferred back to a community level I or level II unit are determined by the infant's underlying medical condition and clinical course while in intensive care. As the infant progresses through the recovery period, the primary care physician should reassess the infant's ongoing medical care needs to determine the infant's readiness for discharge home or if transitional (rehabilitation) or chronic care is required. The decision whether the baby is able to be discharged home or will need chronic care is based on multiple factors, including the infant's ability to effectively feed and demonstrate adequate weight gain, the need for home

oxygen therapy and multiple medications, the need for intensive rehabilitation, the parents' receptivity and ability to care for the infant safely at home, and the availability of home health care services and public health nurse services within the community in which the child will reside. Key to all phases in this process is communication among the treating physicians and staff at the tertiary care center, the receiving primary care physician and the intermediate or primary care nursery staff, and the parents. The receiving physician should speak directly with a member of the treating medical personnel in addition to reviewing a detailed written summary about the infant's medical problems and hospital course. Box 112-2 provides information that should be contained in the transfer summary.

Common medical issues in the continuing care of infants returned to community care after a stay at a level III NICU are discussed in the following sections.

**BOX 112-1 Neonatal Return Transfer to the Community Setting****BENEFITS**

- Provides continuing and convalescent care in the child's home community
- Increases availability of tertiary care beds for other critically ill infants
- Increases opportunities for parent involvement in their infant's care, facilitates parent education, and fosters parent-infant interaction
- May lessen financial burden for the family and reduce health care costs overall
- Promotes communication and collaboration between community health care providers and tertiary care providers

**REQUIREMENTS**

- Infant is hemodynamically stable.
- Appropriate level of care is available closer to the infant's home.
- Individual patient care needs determine the level of continuing care required and the timing of the return transfer.
- Telephone consultation between the receiving health care professional and the perinatal center or community

neonatal intensive care unit staff to initiate the transfer process, prepare the receiving hospital regarding the infant's current medical needs, and develop a treatment plan for the infant.

- The referring center medical staff maintains responsibility for the infant during the transport.
- Parental consent authorizing transfer, treatment, and admission to the receiving center are typically obtained by the referring hospital staff.
- The parents should be encouraged to visit the receiving intermediate or primary care nursery.
- The transport team should communicate with the receiving center regarding the estimated time of arrival.
- On arrival at the receiving hospital the transport team should discuss with the receiving staff the infant's medical history, events during the transport, and the baby's current status and recommended treatment plan.
- A discharge summary from the sending hospital should accompany the infant.
- Periodic communication should be maintained between the referring and receiving hospital personnel.

**BOX 112-2 Information That Should Be Contained in the Transfer Summary**

- Summary of infant's clinical course in the tertiary care unit that reviews each of the infant's medical problems and complications, the treatments received, and ongoing health conditions
- Current medications, nutrition needs, and feeding regimen
- Results of completed diagnostic tests
- Pending test results
- Necessary follow-up testing, including retinopathy of prematurity checks, newborn metabolic and hearing screening, and neuroimaging
- Immunizations received, immunizations due

- Eligibility for and timing of palivizumab administration for the prevention of respiratory syncytial virus infection
- Needed subspecialty consultations and ongoing follow-up care
- Family assessment:
  - Parents' understanding of their infant's health issues
  - Parents' emotional responses and coping style in response to their infant's illness and ongoing health needs
  - Financial and social support resources
- Goals of continued hospital care

**ANEMIA**

Anemia unrelated to underlying hemolytic anemias and congenital red cell disorders is a common medical problem for preterm and sick neonates related to blood loss and decreased red blood cell (RBC) production (ineffective erythropoiesis). (See Chapter 103, The Newborn With Hematologic Abnormalities, for a detailed discussion of neonatal anemia.) Blood losses may be acute or chronic resulting from repeated blood sampling, hemorrhage, and procedure-associated loss. Nutritional deficiencies of protein, iron, folic acid, or vitamin B<sub>12</sub> lead to decreased erythropoiesis. Vitamin E deficiency, common in preterm infants, may lead to increased RBC destruction, particularly in infants receiving supplemental iron. Infection, both acquired

(bacterial or viral sepsis) and congenital (TORCH infections [toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex], parvovirus, HIV, and malaria), may lead to decreased erythrocyte production or increased red cell destruction.

*Anemia of prematurity* typically occurs in infants younger than 32 weeks' gestation and occurs between 2 and 4 months of age. It is the result of low RBC mass, shorter RBC survival, and increased requirements resulting from growth. Premature infants also exhibit more rapid and greater reduction in their hemoglobin levels than do full-term neonates, typically 7 to 8 g/dL. Nearly one-half of preterm infants younger than 32 weeks' gestation will exhibit symptoms from anemia of prematurity. Among very low-birth-weight

**BOX 112-3 Symptoms of Anemia of Prematurity**

- Tachypnea
- Tachycardia
- Bradycardia
- Periodic breathing, apnea, desaturations
- Poor weight gain, feeding difficulties
- Decreased activity
- Pallor
- Flow murmurs
- Metabolic acidosis

infants, 60% to 80% will receive at least 1 transfusion during their hospitalization, most within the first 2 to 4 weeks of life. The decision to transfuse an infant is often based on the infant's underlying health problems and the presence of signs (changes in cardiovascular and respiratory status, increased oxygen or ventilatory support requirements, deterioration in feeding efficiency, and declining weight gain). Box 112-3 lists the signs of anemia of prematurity.

**Transfusion**

Controversy exists in the approach to treating anemia in preterm infants, including a threshold for red cell transfusion, defining symptomatic anemia and the role of erythropoietin in the treatment of anemia of prematurity, and reducing the need for transfusion (Table 112-2). Guidelines from the American College of Pathologists detail thresholds for transfusion based on severity of illness and the degree of technologic support needed by the infant. The use of recombinant human erythropoietin (rHuEPO) to promote erythropoiesis remains controversial because studies have not demonstrated a significant reduction in the transfusion requirements during the first 2 weeks of life, when most transfusions occur in sick neonates. The use of poly packs to split a unit of packed RBCs into multiple aliquots has also reduced the number of donors to which a neonate is exposed. Therefore use of rHuEPO is individualized to selected cases (eg, infants with intrinsic renal disease or infants born to Jehovah's Witness or Rastafarian families who typically refuse blood products for their infants on a religious basis).

Sporadic reports since the 1980s have raised concerns about an association between RBC transfusions required after the first weeks of life and the development of necrotizing enterocolitis (NEC) in very preterm, very low-birth-weight infants. A temporal relationship among anemia, RBC transfusion, and an episode of NEC in up to one-third of transfused infants has been reported in several retrospective studies.

These infants are typically 3 weeks of age or older, were born at younger gestational ages (GAs), and developed symptoms within 48 to 72 hours of the transfusion. Although there are no data demonstrating a causal relationship, it is speculated that transfusion in these infants may cause an immunologic or ischemic

injury to the immature intestine or that the intestine of the preterm infant with clinically symptomatic anemia may be susceptible to injury because of poor tissue oxygenation. A recent case-controlled study noted a reduction in NEC following transfusion in preterm infants if feedings were withheld during the time of transfusion administration.

**Strategies to Prevent and Treat Anemia****Reduce Iatrogenic Blood Loss**

Reducing iatrogenic blood losses that are the result of blood sampling for laboratory testing is important to minimize the infant's transfusion needs. Point-of-care testing devices, validated for use with neonatal blood samples, are valuable tools in reducing blood loss. Unnecessary blood sampling should be avoided as well. Noninvasive monitoring (transcutaneous arterial oxygen saturation [SaO<sub>2</sub>]) is an additional tool that reduces the need for blood sampling. Experts no longer recommend that transfusions be performed to replace phlebotomy losses alone.

If a blood transfusion is required, then the volume of packed red blood cells infused is typically 10 to 15 mL/kg administered via a peripheral intravenous catheter over 2 to 3 hours. The American Association of Blood Banks *Standards for Blood Banks and Transfusion Services*, 29th edition, published in 2014, specifies the testing required for blood donated in the United States.

**Iron Supplementation**

Infants, whether full-term or preterm, require iron supplementation during the first year of life to prevent nutritional anemia. Iron supplementation should provide 2 to 3 mg/kg/day of elemental iron for breastfed infants and babies whose formula intake does not provide the required daily iron intake. Preterm infants need supplementation in the range of 4 to 4.5 mg/kg/day of elemental iron to prevent iron deficiency anemia. During the infant's hospitalization, iron supplementation will often be initiated when the enteral intake is at least 100 mL/kg/day (between 2 and 4 weeks of age). Infants who have required multiple transfusions may receive a significant iron load from the transfused blood. Monitoring of ferritin levels to determine the appropriate time to start iron therapy may be prudent in this circumstance. Vitamins providing nutritional doses of vitamin E (25 IU/day), folate, and vitamin B<sub>12</sub> should also be given daily to high-risk infants.

**APNEA, BRADYCARDIA, AND DESATURATION**

Apnea, bradycardia, and desaturations are common problems encountered in neonatal units. (Box 112-4 provides a list of definitions.) These symptoms may occur in isolation or together. The incidence and severity of apnea increases with decreasing GA. The need to treat neonatal apnea varies with GA and symptoms. AOP is experienced by more than 50% of premature infants and nearly 100% of babies weighing less than 1,000 g at birth. The relationship among apnea, bradycardia, and desaturation is complex and further complicated by the occurrence of 1 or more of these symptoms in relation to feeding or choking episodes.

**Table 112-2** Suggested Guidelines for Packed Red Blood Cell Transfusion in Neonates<sup>a</sup>

HEMATOCRIT, HEMOGLOBIN LEVEL	AMERICAN COLLEGE OF PATHOLOGY RECOMMENDATIONS
Hematocrit (Hct) <0.4 (40%) Hct ≤0.35 (35%) or hemoglobin (Hg) ≤12 g/dL (≤7.44 mmol/L)	Acute blood loss with shock Severe RDS requiring mechanical ventilation, $P_{aw} > 8$ cm H <sub>2</sub> O + $FiO_2 > 0.5$ OR Severe congenital heart disease with cyanosis or heart failure
Hct ≤0.3 (≤30%) or Hg ≤10 g/dL (≤6.2 mmol/L)	Moderate RDS + $FiO_2 > 0.35$ , or nasal cannula oxygen or ventilation with IMV and $P_{aw}$ 6–8 cm H <sub>2</sub> O
Hct ≤0.25 (≤25%) or Hg ≤8 g/dL (≤4.96 mmol/L)	Any of the following conditions: 1. Apnea and bradycardia ≥10 episodes/24 hr or ≥2 episodes requiring bag-mask ventilation 2. Sustained tachycardia >180 beats/min or sustained tachypnea >80 breaths/min over 24-hr period 3. Inadequate weight gain for 4 days with 100 kcal/kg/day (420 kJ/kg/day) caloric intake 4. Mild RDS with: 1. $FiO_2$ 0.25–0.3 2. Nasal cannula 125–250 mL/min 3. IMV or NCPAP with $P_{aw} \leq 20$
Hct ≤0.2 (≤20%) or Hg ≤7 g/dL (≤4.34 mmol/L) and reticulocyte count	Irrespective of the presence or absence of symptoms
HEMATOCRIT LEVEL	AMERICAN ASSOCIATION OF BLOOD BANKS GUIDELINES <sup>b</sup>
Hct <45%	ECMO
Hct <35%	Cyanotic congenital heart disease >35% supplemental O <sub>2</sub> CPAP/intermittent ventilation with MAP ≥6–8 cm H <sub>2</sub> O
Hct <30%	<35% supplemental O <sub>2</sub> O <sub>2</sub> by nasal cannula CPAP/intermittent ventilation with MAP <6 cm H <sub>2</sub> O Significant apnea, bradycardia, tachycardia, or tachypnea Poor weight gain
Hct <20%	Low reticulocyte count Symptomatic anemia

**BOX 112-4** Definitions of Apnea, Bradycardia, and Desaturations

Apnea: Absence of breathing for 20 seconds or more, or more than 10 seconds if associated with bradycardia (heart rate <80 bpm) or desaturation ( $SpO_2$  <80%–85%)

Apnea classification:

- Central: cessation of chest wall movement (inspiration) caused by lack of central nervous system neural input (10%–25%)
- Obstructive: respiratory effort without nasal airflow (10%–20%)
- Mixed: combination of central and obstructive apneas (50%–70%)

Bradycardia: Age-related norms have been defined for infants based on postmenstrual and postnatal age

Significant bradycardia in infants less than 44 weeks postmenstrual age: less than 80 bpm for more than 15 seconds or less than 60 bpm for 5 seconds

Desaturation: Oxygen saturation less than 80%–85% for more than 4 seconds (normal range for full-term and preterm infants from birth to 28 days of age: 93%–100%; mean oxygen pressure 70–76 mm Hg during postnatal days of life 2–7)

- May accompany periodic breathing (respiratory pauses)
- May or may not occur in association with bradycardia

Periodic breathing: Episode of 3 or more successive respiratory pauses of 3 seconds or more in duration, each separated by 20 or more seconds of normal respiration

Periodic breathing is considered significant if it occurs during more than 5% of the quiet sleep time

Derived from Finer NN, Higgins R, Kattwinkel J, et al. Summary proceedings from the Apnea of Prematurity Group. *Pediatrics*. 2006;117(3):547–551; Ramanathan R, Corwin MJ, Hunt CE, et al, and the Collaboration Home Infant Monitoring Evaluation (CHIME) Study Group. *JAMA*. 2001;285(17):2199–2207.

The criteria used to define *clinically significant* apnea, bradycardia, and desaturation are controversial, presenting a challenge to the physician caring for preterm infants who exhibit these symptoms. Apnea in the larger preterm infant typically resolves by 34 to 36 weeks postmenstrual age (PMA), with over 90% of infants being apnea free by 37 weeks PMA. Among extremely low-birth-weight infants less than 28 weeks' gestation, apnea duration is longer, often not resolving until 40 to 43 weeks PMA.

Despite numerous studies, consensus as to the optimal SaO<sub>2</sub> range has not been achieved. Earlier study outcomes for infants born at less than 27 weeks' gestation have demonstrated improved survival rates and reduced morbidity (chronic lung disease, ROP) without an increase in cerebral palsy among infants who are maintained with SaO<sub>2</sub> in the range of 84% to 94%. The recent international, multicentered BOOST (Benefits of Oxygen Saturation Targeting) II and SUPPORT (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments) trials designed to evaluate the efficacy of tightly controlling oxygen saturation in extremely preterm infants less than 28 weeks' gestation have identified higher survival rates at 36 weeks PMA of infants born at less than 28 weeks of gestation and randomly assigned to oxygen saturation (SpO<sub>2</sub>) targets of 91% to 95% rather than 85% to 89% while breathing supplemental oxygen. A recent meta-analysis of the SUPPORT, BOOST and Canadian Oxygen (COT) trials demonstrated that more restrictive oxygen saturation SpO<sub>2</sub> targets of 85% to 89% versus 91% to 95%, though associated with lower rates of ROP and a slight trend toward reduced chronic lung disease, contributed to higher rates of death and necrotizing enterocolitis.

There are no data relating specific SaO<sub>2</sub> levels and the incidence or frequency of apnea. However, apnea frequency is increased in the presence of lower oxygen saturations. Until more definitive data are available, prudence suggests maintaining SaO<sub>2</sub> levels in the range of 90% to 94% (alarm limits 88%–96%) for infants at 32 weeks or less GA and between 92% and 97% for preterm infants 33 weeks or more GA (alarm limits 90%–98%).

Preterm infants with lung disease often have SpO<sub>2</sub> measurements less than 90% lasting less than 20 seconds. These episodes often occur during feedings and periods of wakefulness and sleep and are not associated with apnea, bradycardia, or cyanosis. Infants with chronic lung disease are more likely to have severe desaturations less than 80%. Episodes of prolonged desaturation (SpO<sub>2</sub> ≤80%) for more than 4 seconds are most often seen during periodic breathing or hypoventilation. Experts suggest that infants less than 34 weeks' gestation receive cardiorespiratory monitoring and pulse oximetry for apnea and bradycardia during their hospitalization. Desaturations or bradycardia occurring without apnea suggest airway obstruction (obstructive apnea).

### Evaluation of Apnea, Bradycardia, or Desaturation

Evaluation of the infant with apnea, bradycardia, or desaturations will vary with the frequency and severity of the infant's symptoms. Although primarily related to

the infant's underlying prematurity, other causes must be considered, including infection, anemia, hyperthermia (environmental overheating), seizures, necrotizing enterocolitis, metabolic abnormalities (hypoglycemia, acidosis, hyponatremia, hypocalcemia, inborn errors of metabolism), and patent ductus arteriosus or heart failure. Excessive neck flexion may also trigger apneic or bradycardic episodes. The use of sedation, analgesia, and other medications may contribute to respiratory depression and apneic episodes. Acute stress such as that experienced by preterm infants undergoing an eye examination for ROP or after multiple procedures occurring on the same day may contribute to fatigue and an increase in feeding intolerance or apnea, bradycardia, or desaturations in the hours after the procedure. Increased symptoms may be exhibited irrespective of whether the infant receives sedation before the procedure. Gastroesophageal reflux (GER), another common condition among preterm infants, is also thought to contribute to AOP. Although the 2 conditions often occur coincidentally, recent studies have failed to demonstrate a causal link between these 2 conditions in premature infants. Increased frequency of apnea, bradycardia, and desaturations has been observed in very preterm infants following primary immunization at 2 months chronologic age. Preterm infants at highest risk are those of younger GA and those with more medical complications and pre-existing apnea. The frequency of apnea is also more common when multiple vaccines are administered. Consequently, cardiorespiratory monitoring is recommended for a period of 48 hours following primary immunization of very preterm infants.

### Treatment of Apnea, Bradycardia, and Desaturation

Treatment of apnea, bradycardia, and desaturation will depend on the underlying cause or causes for the symptomatology. In addition to diagnosing and treating precipitating conditions, therapy may include the use of tactile stimulation, nasal cannula with air-oxygen flow, nasal continuous positive airway pressure (CPAP), methylxanthines, or mechanical ventilation alone or in combination.

### Medications

Aminophylline, theophylline, and caffeine are the methylxanthines most often used in the treatment of significant AOP (Box 112-5). Caffeine is considerably less toxic than theophylline and is the drug of choice for treating neonatal apnea. Treatment is deemed effective if the reduction in episodes of apnea is 50% or greater. The effectiveness and safety of caffeine treatment and lack of side effects have been confirmed in a 5-year, multicenter, multinational randomized clinical trial. An additional benefit of caffeine therapy is improved brain white matter development and motor outcome through 5 years of age among infants treated with caffeine. Signs of methylxanthine toxicity include tachycardia, gastrointestinal intolerance, and jitteriness or agitation. Medications can usually be discontinued when the preterm infant reaches 32 to 34 weeks PMA and has been apnea free for 7 to 10 days. Infants treated with caffeine require monitoring for 7 days because of caffeine's long half-life. The period of

### BOX 112-5 Methylxanthines Used to Treat Apnea of Prematurity

#### CAFFEINE

- Loading dose: 10 mg/kg IV or PO (20 mg/kg caffeine citrate)
- Maintenance dose: 2.5 mg/kg every 24 hr
- Therapeutic plasma level 8 to 20 mg/L
- Mean half-life is approximately 100 hours and remains prolonged until 37 to 38 weeks postmenstrual age; caffeine half-life decreases with maturity and postnatal age
- Infants with cholestasis have longer caffeine half-life caused by impaired hepatic metabolism
- Long-term administration associated with increased oxygen consumption and reduced weight gain

#### AMINOPHYLLINE OR THEOPHYLLINE

- Aminophylline is metabolized to theophylline (80% theophylline)
- Loading dose: 4 to 6 mg/kg IV or PO
- Maintenance dose: 6 mg/kg/day divided every 6, 8, or 12 hours IV or PO
- Therapeutic plasma level: 6 to 11 mg/L (theophylline)
- Plasma half-life 12 to 64 hours

IV, intravenous; PO, by mouth.

observation after discontinuation of theophylline is somewhat shorter, at 4 to 5 days.

### Noninvasive Ventilation

Noninvasive ventilation (NIV) has become a primary form of respiratory support for preterm and sick infants with respiratory illness including lung immaturity, retained fetal lung fluid (TTN), and apnea of prematurity. There are 2 forms of NIV commonly used: CPAP delivered either through a continuous-flow (continuous positive pressure across the respiratory cycle) device or through a variable-flow device with phasic ventilation (continuous positive pressure with the addition of periods of increased airway pressure [or breaths]), typically referred to as nasal intermittent positive pressure ventilation (NIPPV). NIV stabilizes the airways, alveoli, diaphragm, and chest wall; increases lung volumes; and decreases airway resistance and the work of breathing. NIV facilitates extubation from mechanical ventilation and results in less post-extubation failure (need for reintubation). It also has been shown to reduce the incidence and severity of apnea and bradycardia, reduce the risk of ventilator-associated pneumonia, and improve survival in infants weighing less than 1,500 g with respiratory distress syndrome (RDS). In combination with surfactant administration, NIV shortens the time on mechanical ventilation, thus causing less chronic lung disease. In 2014, the AAP published a policy statement on Respiratory Support for the Preterm Infant

**Figure 112-1** Premature infant on nasal continuous positive airway pressure.

at Birth. Care recommendations included that CPAP started at or soon after birth with subsequent selective surfactant administration may be considered as an alternative to routine intubation with prophylactic or early surfactant administration in preterm infants; and (2) that infants with RDS may vary markedly in the severity of the respiratory disease, maturity, and presence of other complications, and thus it is necessary to individualize patient care.

### Continuous Positive Airway Pressure

CPAP is a commonly used noninvasive respiratory support modality in the care of neonates with transitional difficulties and premature infants with RDS, chronic lung disease, and AOP. CPAP is provided through short binasal prongs (NCPAP), nasopharyngeal tube (NP-CPAP), or infant nasal mask (NM-CPAP) used in conjunction with a continuous flow source (underwater seal, bubble CPAP) or an infant or multipurpose ventilator equipped with a CPAP mode (Figure 112-1). These CPAP devices provide heated and humidified continuous or variable flow in order to increase an infant's functional residual capacity, improve lung compliance, and decrease airway resistance. The resultant increase in tidal volume reduces the infant's work of breathing and stabilizes minute ventilation. In addition, CPAP reduces pharyngeal and airway collapse, stabilizes chest wall musculature, and decreases chest wall inhibitory reflexes. CPAP is effective in mixed and obstructive apnea. Indications for CPAP use in infants include the presence of abnormalities on physical examination, inadequate arterial blood gases, poor lung expansion on chest radiograph, and conditions that are known to benefit from CPAP (Box 112-6, Box 112-7). The duration of CPAP therapy, typically applying 4- to 6-cm water ( $H_2O$ ) pressure, will depend on the reason for its use and the infant's stability as the CPAP is weaned to physiologic levels (3 cm  $H_2O$ ).

Complications associated with CPAP use include nasal irritation and nasal septal erosion, abdominal distention, and feeding intolerance. Barotrauma and

**BOX 112-6 Continuous Positive Airway Pressure Indications**

- Increased work of breathing; respiratory rate 30% above the normal for age
- Retractions, grunting, and nasal flaring
- Presence of cyanosis, pallor, and respiratory distress
- Inadequate arterial blood gas values; inability to maintain partial pressure of oxygen greater than 50 mm Hg with an  $\text{FiO}_2$  less than 0.25 and partial pressure of carbon dioxide higher than 50–55

$\text{FiO}_2$ , fraction of inspired oxygen.

**BOX 112-7 Conditions Benefiting From Continuous Positive Airway Pressure**

- Apnea of prematurity
- Atelectasis
- Pulmonary edema
- Respiratory distress syndrome
- Recent extubation
- Tracheomalacia or similar lower airway abnormality
- Transient tachypnea of the newborn

air leaks may also result if excessive pressure is applied or if an inappropriate CPAP device is used. Overdistention of alveoli will impair ventilation-perfusion ratios and lead to decreased oxygenation and carbon dioxide retention and may also reduce cardiac output and cause an air leak. Insufficient gas flow through the CPAP device creates a fluctuating baseline pressure that can increase the infant's work of breathing. Nasal prong obstruction may occur from accumulated secretions or bleeding after traumatic suctioning or nasal irritation. Humidification and gentle suctioning are important aspects of care for infants requiring CPAP to prevent nasal mucosal damage. Proper positioning of the CPAP prongs and correct nasal prong size are additional factors important to ensuring effective CPAP therapy. The infant's head position is also important because excessive head rotation or neck extension can lead to altered effective CPAP pressure. Maintaining a closed-mouth position is also important to ensuring that the infant is receiving the prescribed positive airway pressure and oxygen concentration. Studies have demonstrated that a 2.2-cm  $\text{H}_2\text{O}$  drop in CPAP pressure occurs from the CPAP prongs to the pharynx with the mouth closed. This pressure loss increased to 3.2 cm  $\text{H}_2\text{O}$  when the infant's mouth was open. Gastric and abdominal distention are common complications of CPAP therapy and may contribute to feeding tolerance problems or aspiration.

**High-Flow Nasal Cannula**

Heated, humidified, high-flow nasal cannula (HFNC) is another noninvasive respiratory support modality used in the management of preterm infants with lung disease. Some neonatologists also use HFNC as a treatment strategy in preterm infants with AOP. HFNC refers to the delivery of heated, humidified, and blended oxygen/air via small caliber nasal cannulae (NC) at flow rates of  $>1$  L/min. NC at flow rates as low as 1 to 2.5 L/min is associated with increased pharyngeal pressure and can deliver positive distending pressure in preterm neonates. HFNC is as effective as nasal CPAP in the management of AOP as well as RDS in infants 28 weeks or more GA. However, there is a potential for asynchrony in the infant's breathing that may cause respiratory fatigue over time. If used, frequent assessment of the infant's work of breathing is important. Although HFNC may be a less intensive intervention, infants receiving it should still be monitored (eg, with capillary blood gases or chest radiographs) as they would on CPAP. Laboratory studies evaluating the effect of HFNC flow rate, nasal cannula size, the percentage occlusion of the nares by different sized cannula, and the degree of mouth occlusion have demonstrated that airway pressure progressively increased with both increasing HFNC flow rate and nasal prong-to-nares ratio. In clinical studies of extremely low-birth-weight infants, HFNC has been shown to deliver high pharyngeal pressures. Thus, use of HFNC in infants less than 1,000 g is not recommended and remains controversial among infants between 1,001 and 1,500 g.

**BRONCHOPULMONARY DYSPLASIA (CHRONIC LUNG DISEASE)**

Bronchopulmonary dysplasia (BPD) develops in one-third of very low-birth-weight infants (rates of BPD vary with NICU care practices and approaches to ventilatory support) and is most common among infants less than 32 weeks' gestation. In addition to higher mortality rates, infants with BPD experience greater morbidity. Changes in clinical practice, particularly restriction in postnatal steroid usage caused by concerns about higher rates of cerebral palsy among infants receiving early postnatal corticosteroids, have resulted in increased numbers of very low-birth-weight infants surviving with BPD. (For detailed information on BPD, see Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn.)

BPD is defined by oxygen dependence at specific periods after birth (28 days postnatal age or 36 weeks PMA) among infants with persistent lung disease and characteristic radiographic findings (Box 112-8). Characteristic BPD findings have changed over time as the disease, originally described in larger preterm infants with severe RDS who required treatment with mechanical ventilation with high pressures (tidal volumes) and high oxygen concentrations, has evolved to include more immature infants with mild to moderate lung disease who exhibit prolonged oxygen requirements. Currently, classic BPD, the form of chronic lung disease resulting from severe RDS and leading to

### BOX 112-8 Definitions of Bronchopulmonary Dysplasia (BPD)

- Oxygen (O<sub>2</sub>) requirement at 28 days of age
- O<sub>2</sub> requirement at 36 weeks postmenstrual age (PMA)
- O<sub>2</sub> or positive airway pressure requirement at 36 weeks PMA
- O<sub>2</sub> requirement at 36 weeks PMA with more than 28 days of oxygen therapy duration
- National Institutes of Child Health and Human Development (2001) severity-based definition of BPD for infants less than 32 weeks GA

**Mild BPD**—need for supplemental O<sub>2</sub> for 28 days or more but not at 36 weeks PMA or hospital discharge if the infant is less than 36 weeks PMA

**Moderate BPD**—need for supplemental O<sub>2</sub> for 28 days or more plus treatment with less than 30% O<sub>2</sub> at 36 weeks PMA

**Severe BPD**—need for O<sub>2</sub> for 28 days or more plus 30% or more O<sub>2</sub> and/or positive pressure at 36 weeks PMA

### BOX 112-9 Complications Associated With Bronchopulmonary Dysplasia

- Apnea
- Reactive airway disease
- Infection
- Feeding difficulties
- Gastroesophageal reflux
- Poor growth
- Poor bone mineralization (osteopenia, nutritional rickets)
- Electrolyte abnormalities
- Nephrocalcinosis
- Impaired cardiac function: pulmonary hypertension, cor pulmonale, left ventricular hypertrophy
- Systemic hypertension
- Poor cognitive and motor outcomes
- Retinopathy of prematurity

atelectasis, edema, fibrosis, smooth muscle disease, right-ventricular hypertrophy, and the need for prolonged ventilation, develops in fewer than 25% of babies with BPD. Most infants with BPD exhibit milder RDS signs of hazy lungs, minimal airway lesions, pulmonary edema, and disruption of lung growth and alveolarization, and require prolonged oxygen, CPAP therapy, or both. Complications associated with BPD are listed in Box 112-9.

## Oxygen Therapy

Oxygen therapy is an important component of BPD management. Oxygen may be delivered to convalescing infants through various devices: oxygen hood, nasal cannulae (high- and low-flow cannulae), CPAP devices, or conventional ventilators. Precise measurement of the oxygen concentration delivered to the infant is not as easily determined when a baby is on a nasal cannula or CPAP. The actual oxygen concentration received by the infant reflects a blend of the nasally inspired oxygen and ambient (room) air inhaled through the nose and mouth. The infant's minute ventilation and ratio of nose-to-mouth breathing also alter the effective fraction of inspired oxygen (FiO<sub>2</sub>) received. This consideration is important during the process of weaning an infant from supplemental oxygen therapy and in determining whether a need exists for home oxygen use. Approximately two-thirds of convalescing infants can be successfully weaned from supplemental oxygen when the infant's SpO<sub>2</sub> is greater than 96% and the FiO<sub>2</sub> is less than or equal to 0.23. A simplified formula for calculating the oxygen level delivered to the infant's hypopharynx has been devised that uses the infant's weight, nasal cannula flow, and FiO<sub>2</sub>:  $0.21 + (\text{flow} + \text{weight}) \times (F_{\text{NCO}_2} - 0.21)$ , where  $F_{\text{NCO}_2}$  is the FiO<sub>2</sub> set to be delivered via the nasal cannula.

Care must be taken when providing flow through a nasal cannula because positive distending pressure has been demonstrated in premature infants weighing less than 2,000 g when nasal cannula flow rates of 1 to 2 L/min are used. Nasal cannula prong diameter is another factor in the delivery of positive distending pressure because a 0.3-cm nasal cannula has been shown to deliver increased pressure as a function of the flow rate used. It is also important to recognize that the need for supplemental oxygen or air flow support (low-flow nasal cannula with FiO<sub>2</sub> 0.21) at 36 weeks PMA may be multifactorial, reflecting an interaction between abnormal lung tissue function caused by BPD and continuing immature respiratory control. Infants with significant chronic lung disease also may be particularly susceptible to developing periodic breathing when they become hypoxemic with even brief central apneas.

## Oxygen Saturation

Maintaining the arterial pressure of oxygen (PaO<sub>2</sub>) levels above 55 torr (mm Hg) is important for infants with chronic lung disease. Infants with BPD may exhibit increased oxygen requirements during nipple feeding and sleep if significant desaturations (SpO<sub>2</sub> <85%) occur during pulse oximetry. The issue of SpO<sub>2</sub> limits (oxygen targeting) is the focus of debate and ongoing study. Results from recent multicentered trials in the US, UK, and Australia on SpO<sub>2</sub> and its role in developmental outcome, as well as the incidence and severity of ROP and BPD in extremely premature babies, continue to be elucidated. The conundrum is that optimal oxygen thresholds to protect the developing eye may be harmful to the cardiovascular and respiratory function of the infant with BPD. Hypoxemia is detrimental to the baby with BPD because it leads to increased pulmonary vascular resistance, pulmonary vasoconstriction, impaired

right-ventricular performance, and peripheral oxygen delivery. Further chronic hypoxemia affects brain growth and weight gain.

When caring for a premature infant with BPD who is less than 35 weeks PMA, the SpO<sub>2</sub> range should be maintained between 90% and 95%. Tighter SpO<sub>2</sub> limits in the range of 92% to 94% are recommended but have been shown to be difficult for many nurseries to attain. An SpO<sub>2</sub> of 94% to 98% for infants with BPD who are more than 35 weeks PMA is recommended to reduce the risk of pulmonary hypertension. During sleep the SpO<sub>2</sub> should be kept above 93% because this level has been shown to improve sleep architecture. In the STOP-ROP study evaluating the efficacy of 2 supplemental oxygen strategies to prevent the development of threshold ROP in preterm infants with BPD, maintaining SpO<sub>2</sub> levels above 96% was shown to increase the risk for adverse pulmonary and cardiovascular outcomes and resulted in a longer duration of oxygen treatment, medication use (diuretics, methylxanthines, and steroids) and hospitalization. However, the infant with BPD and pulmonary hypertension requires adequate oxygen to reduce the pulmonary vascular resistance and avoid death. Current recommendations for these infants are to avoid SpO<sub>2</sub> less than 93% and maintain saturation pressure levels between 94% and 98%.

### Monitoring

In addition to impairing right-ventricular heart function, BPD is associated with other cardiovascular abnormalities: left-ventricular hypertrophy, systemic hypertension, and the development of bronchial and other systemic-pulmonary collateral vessels. Postnatal steroid use may also contribute to the development of transient left-ventricular hypertrophy. Pulse oximetry is an important tool used in the routine monitoring of infants with chronic lung disease while they remain in the hospital. Monitoring should occur through all of the infant's activities of daily living—while awake, during bathing and feeding, and during active and quiet sleep. Blood pressures should be monitored at least weekly, and periodic electrocardiograms should be obtained to evaluate the infant for right-ventricular hypertrophy. Infants requiring prolonged positive pressure and/or oxygen therapy or who have evidence of pulmonary hypertension should have serial echocardiography performed every 2 to 3 months.

### Medications

Medications used in the treatment of BPD include aerosolized beta-agonists, inhaled steroids, and diuretics (Box 112-10). The duration of medication use is predicated on the infant's clinical symptoms, tolerance of fluid volumes and growth, and continued dependence on oxygen or respiratory support. The effectiveness of bronchodilator therapy in preterm infants is unclear. Studies have demonstrated short-term improvement in respiratory function with treatment. However, long-term benefits in the treatment of BPD have not been conclusively demonstrated in randomized, controlled studies. For infants with worsening respiratory symptoms such as wheezing, increasing airway resistance, or worsening lung compliance, the

### BOX 112-10 Medications Used in the Treatment of Bronchopulmonary Dysplasia

#### DIURETICS

- Hydrochlorothiazide: 20 to 40 mg/kg/day in 2 divided doses every 12 hours
- Spironolactone: 2 to 4 mg/kg/day in 2 divided doses every 12 hours
- Furosemide: 2 to 4 mg/kg/dose every 12 to 24 hours
- Potassium chloride: 1 to 4 mEq/kg/day in 2 to 4 doses every 6 to 12 hour

#### BRONCHODILATORS

- Albuterol: 0.5 cc by nebulizer or inhaler every 6 to 12 hours
- Ipratropium: 0.5 cc by nebulizer or inhaler every 12 hours
- Levalbuterol: 0.62 mg respule by nebulizer

#### ANTI-INFLAMMATORY AND INFLAMMATORY DRUGS (inhaled steroids)

- Cromolyn: inhaler or nebulizer; takes 2 to 4 weeks for adequate trial
- Budesonide: 0.25 to 0.5 mg respule every 12 to 24 hours
- Fluticasone: 0.125 mg (1 puff) every 12 hours
- Betamethasone valerate
- Oral prednisone for serious exacerbations

physician should consider a closely monitored trial of albuterol and ipratropium. The preferred mode of drug delivery is through a metered-dose inhaler plus spacer rather than nebulizer or via hand-bag ventilation. Consultation with a neonatologist or pediatric pulmonary specialist can assist in implementing and monitoring the efficacy of respiratory management strategies.

## NUTRITION AND GROWTH

### Premature Infant

Continuing care of the recovering infant or growing premature baby includes optimizing the infant's growth and nutrition. Increased calories, protein, and mineral intake are needed to promote better linear growth and mineral accretion in the very preterm. The recommended caloric intake will vary with the infant's underlying medical issues and degree of prematurity. Caloric requirements for most infants will range from 100 to 120 kcal/kg/day to achieve an average daily weight gain of 20 to 30 g. For the preterm baby, weight gains of 15 to 25 g/day are more typical between 28 and 32 weeks of gestation. As infants recover, more of their caloric intake is available for tissue growth and weight gain. However, during periods of increased energy expenditure, such as when the infant is weaning from CPAP or oxygen, transitioning from isolette-bassinette conditions, learning to nipple feed, or experiencing an intercurrent illness, growth may slow or the infant may lose weight. Energy requirements for

infants with chronic lung disease have been shown to be 25% higher than for preterm infants without BPD. Consequently, infants with chronic lung disease require 120 to 160 kcal/kg/day. The caloric density of the feeding will depend on the infant's growth velocity, feeding efficiency, evidence of feeding fatigue, and ability to handle fluid volume.

The rate of weight gain and adequacy of growth are a significant concern in the care of the preterm infant because suboptimal growth will affect brain growth and cognitive outcomes; however, excessively rapid growth has the potential to predispose the infant to cardiovascular problems in adulthood. A common practice involves restricting the feeding volume until a weight plateau occurs before increasing the feeds. This factor is important in the growth delay experienced by many preterm infants. Common patterns of growth in preterm infants are listed in Box 112-11.

Achieving optimal postnatal growth is a challenge as growth lags considerably after birth among most very low-birth-weight infants. Figure 112-2 depicts an aggressive nutritional approach to prevent poor postnatal growth in very low-birth-weight infants. Nutrient intakes that meet current recommended daily intakes are difficult to achieve during early postnatal life. By the end of the first week, significant cumulative energy and protein deficits occur in preterm infants, irrespective of GA. Among the smallest infants, weight loss often exceeds 15% of their birth weight. Energy and protein deficits persist at 5 weeks of age; infants of 30 weeks' gestation or younger exhibit mean energy deficits of 813 kcal/kg and protein deficits of 23 g/kg. Among infants older than 30 weeks' gestation, comparable energy and protein deficits are evident at the end of the first week of life, although by 5 weeks of age these infants' energy and protein deficits are 382 kcal/kg and 13 g/kg, respectively. Evidence is increasing of long-term consequences for these children who remain shorter, weigh less, and have a greater risk of neurodevelopmental impairment than their normal-birth-weight full-term counterparts. As GA decreases, an incremental lag occurs in weight gain and growth velocity (Figure 112-3 and Figure 112-4). Infants with subnormal head circumferences at 8 months

corrected age have an increased risk of neurologic impairment, lower IQ, and poorer academic performance. Male infants are more likely at greatest risk for extrauterine growth restriction, require mechanical ventilation during the first day of life, need respiratory support at 28 days of age, develop necrotizing enterocolitis, and receive postnatal steroids.

The length of time required to regain birth weight is an important predictor of the overall rate of weight gain and of the likelihood that an infant will be below the 10th percentile at the time of hospital discharge. Early initiation of parenteral nutritional support and enteral feeding is critical. Trophic and minimal enteral feedings promote intestinal motility and bile secretion and induce lactase activity, reducing sepsis and cholestasis. Early aggressive nutrition regimens limit the degree of extrauterine growth restriction and improve the postnatal metabolic and nutritional status of the infant. Daily volume increments of 10 to 35 cc/kg/day have been shown to be safe. More rapid advancement of feedings (25–35 cc/kg/day) results in a shorter time to regain birth weight without an increase in the rate of necrotizing enterocolitis. After regaining birth weight, the weight gain goal for a preterm infant is 14 to 16 g/kg/day. Once the infants reach readiness for discharge, the weight gain goal is 20 to 30 g/day.

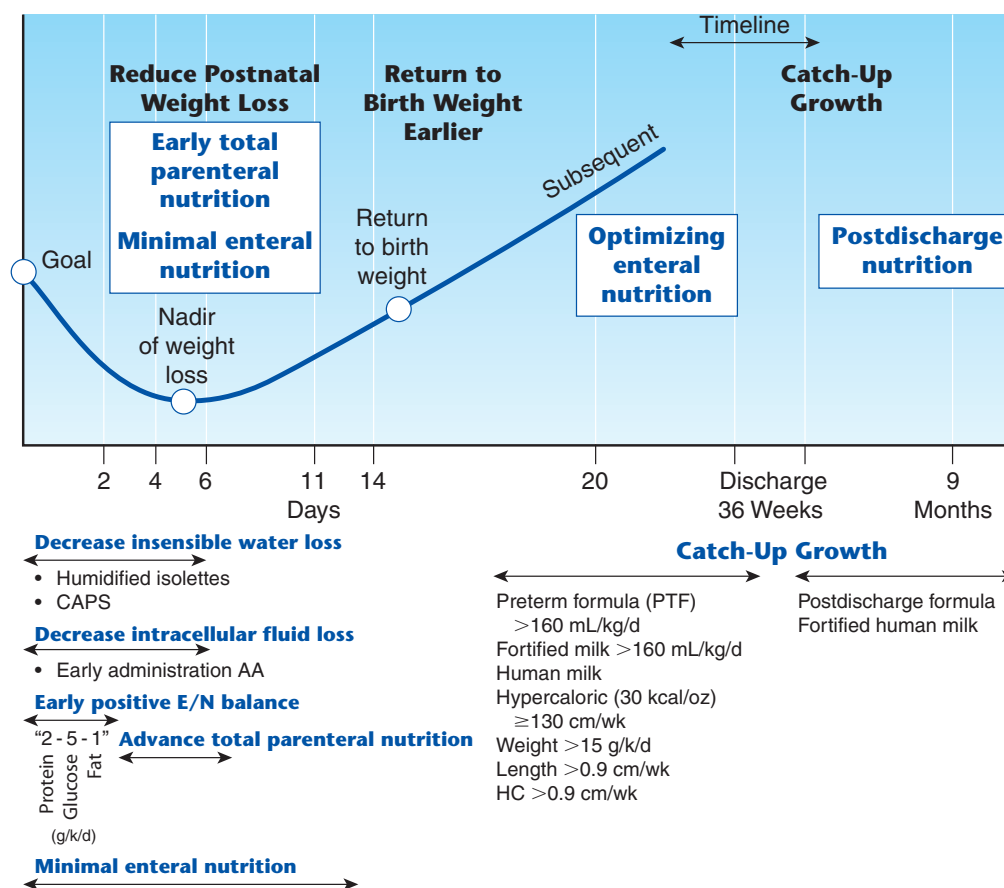

Just as inadequate growth is detrimental, excessive weight gain, rapid growth velocity, and growth patterns that alter the body's composition have harmful long-term cardiovascular and metabolic effects. The postnatal environment, nutrient energy sources, hormones, and factors that influence growth during the postnatal period differ from the intrauterine condition. After birth, fat becomes the primary fuel source for the neonate, in contrast to fetal dependence on glucose, lactate, and amino acids. Very preterm infants younger than 32 weeks' gestation also have decreased insulin sensitivity. The rate of postnatal weight gain in preterm infants is dependent on caloric intake, whereas brain growth and increasing length are influenced by the infant's protein intake. Fat accretion is increased postnatally in preterm infants who at term-postmenstrual age have a higher body fat content and more visceral fat than normal-birth-weight full-term infants. An important consideration in planning a nutritional support program for the recovering and growing low-birth-weight infant is recognizing that a pattern of rapid catch-up growth during the first 2 years of life and an observed increase in central fat distribution at 5 years of age in these children predispose them to cardiovascular disease and metabolic syndrome in later life.

Infants who are returned to community neonatal units for continuing and convalescent care will vary in their nutritional needs, as well as their mode of nutritional intake at the time of back transfer. Some infants may be on full enteral feeding, whereas others may be transitioning from parenteral nutrition (PN) to enteral feedings. Specific nutrient requirements will be influenced by the infant's underlying medical problems and degree of prematurity and whether the nutrient sources are from parenteral fluids, breast milk, or

### **BOX 112-11** Convalescing Preterm Infant Growth Patterns

- Appropriate-for-gestational-age (AGA) infant at birth who at discharge has a body weight that is appropriate for the PMA (corrected age)
- AGA preterm infant at birth whose discharge weight is below the reference for the PMA (postnatal or extrauterine growth restriction)
- Small-for-gestational-age (SGA) infant who remains below the 10th percentile for PMA at the time of discharge
- SGA infant who exhibits early postnatal catch-up growth and whose weight at discharge is appropriate for postmenstrual age

**Figure 112-2** Aggressive nutrition to prevent extrauterine growth restriction. (From Adamkin DH. Nutrition management of the very low-birth-weight infant I. Total parenteral nutrition and minimal enteral nutrition. *NeoReviews*. 2006;7:e602–e607.)

**Figure 112-3** Longitudinal growth of hospitalized very low-birth-weight infants. (From Ehrenkranz RA, Younes N, Lemons JA, et al. Longitudinal growth of hospitalized very low birth weight infants. *Pediatrics*. 1999;104:280–289.)

**Figure 112-4** Growth curves of appropriate-for-gestational-age and small-for-gestational-age, very low-birth-weight infants versus postnatal age (days). A systematic review and meta-analysis to revise the Fenton growth chart for preterm infants. *BMC Pediatr.* 2013;13:59. © Fenton and Kim; licensee BioMed Central Ltd. 2013. Available at: <http://bmcpediatr.biomedcentral.com/articles/10.1186/1471-2431-13-59>. Accessed January 28, 2016.)

infant formula. Use of standardized feeding protocols has been shown to optimize nutritional intake, promote weight gain, and reduce the risk of extrauterine growth restriction.

Weekly assessment of growth should include plotting the infant's weight, length and head circumference on one of the commonly used postnatal growth charts (Fenton growth charts, Figure 112-5 and Figure 112-6; or Olsen growth charts, Figure 112-7).

### Parenteral Nutrition

Parenteral nutrition solutions may be administered via peripheral or central intravenous lines. Table 112-3

and Table 112-4 list considerations in calculating PN solutions.

The ratio of calories to grams of nitrogen is important to promote optimal nitrogen utilization for protein synthesis and tissue growth. The optimal energy-to-protein ratio is 150 to 200 nonprotein cal to 1 g of nitrogen, or 22 kcal/g of protein. The total grams of amino acids per day are divided by the factor 6.25 to yield the grams of nitrogen per day: ratio = nonnitrogen calories ÷ grams of nitrogen.

Increased calories are needed during episodes of metabolic stress. Table 112-5 lists the effects of certain diseases on specific nutrient requirements.

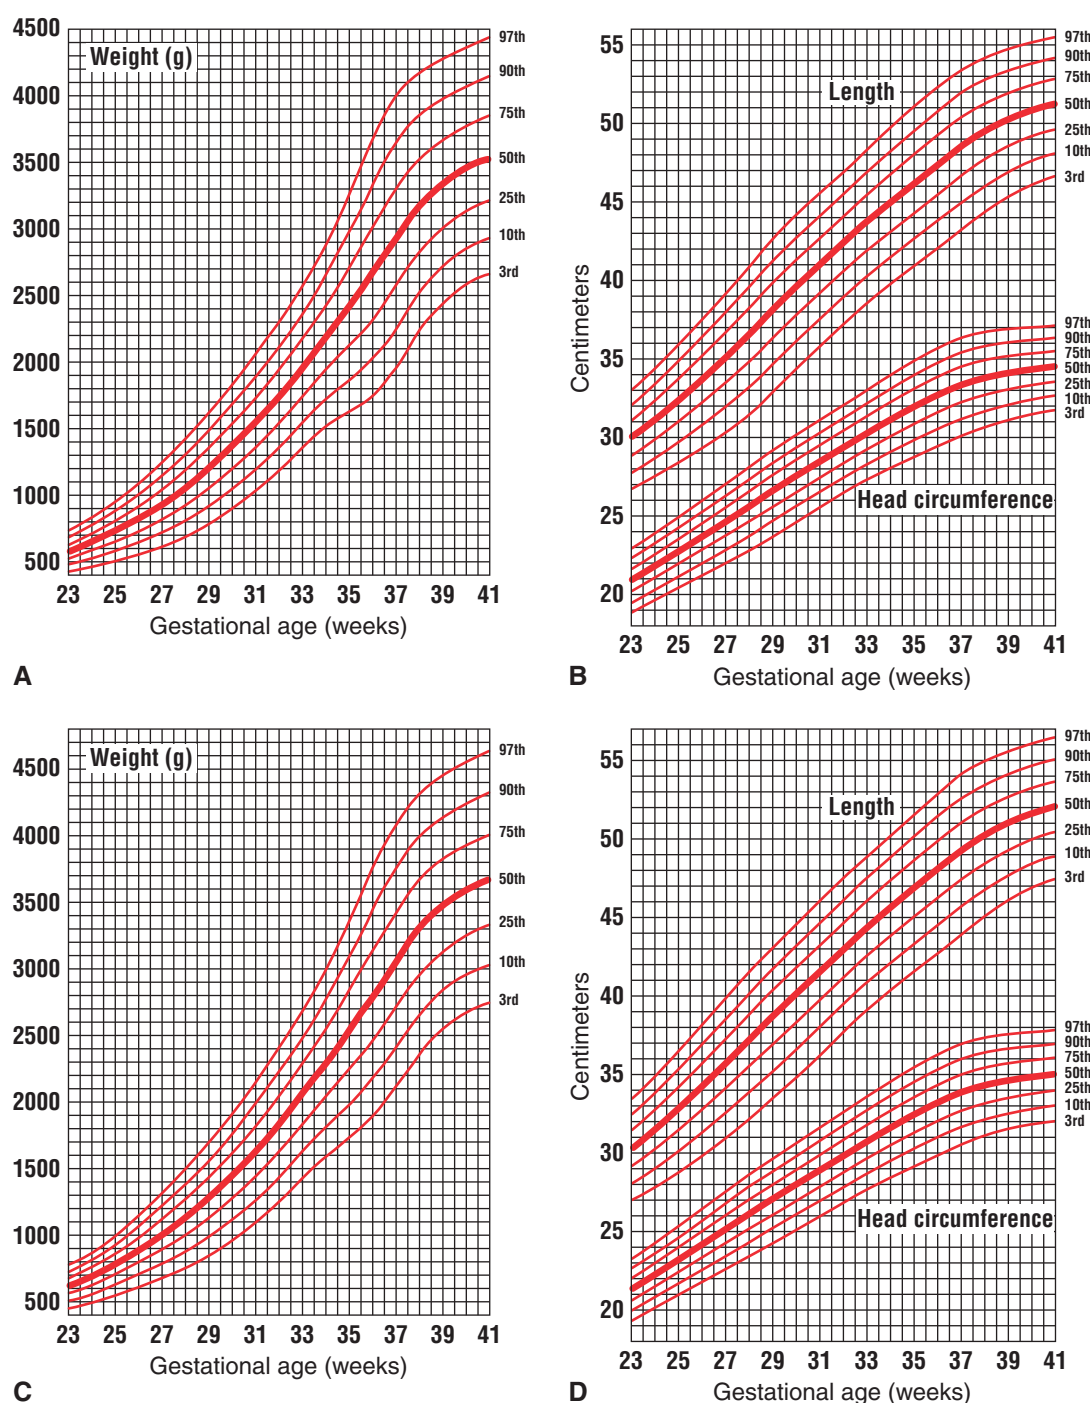

**Figure 112-6** Fetal-infant growth chart for preterm infants—boys (curves equal the male WHO Growth Standard at 50 weeks). (From Fenton TR, Kim JH. A systematic review and meta-analysis to revise the Fenton growth chart for preterm infants. *BMC Pediatr.* 2013;13:59. © Fenton and Kim; licensee BioMed Central Ltd. 2013. Available at: <http://bmcpediatr.biomedcentral.com/articles/10.1186/1471-2431-13-59>. Accessed January 28, 2016.)

In brief, nutritional requirements are altered as follows:

- + 12% for every degree fever
- + 20% to 30% for infants requiring surgery
- + 40% to 50% for septic infants
- + 50% to 100% for infants with long-term growth failure

Peripheral PN solutions cannot exceed 12.5% dextrose or 3.0% to 3.5% amino acid; maximal calcium concentration is also limited because of the risk of severe tissue injury in the event of extravasation. Each gram of protein provides 4 kcal. Potential risks associated with protein administration include acidosis,

elevated blood urea nitrogen, hyperammonemia, and cholestasis. Taurine and cysteine are considered conditional essential amino acids for neonates and should be added to PN solutions; particularly for very preterm (<32 weeks' GA)/very low-birth-weight (<1,500 g) infants. Dextrose yields 3.4 kcal/g and may be advanced to provide a maximal glucose infusion rate of 12 to 14 mg/kg/min. Complications associated with dextrose infusions include hyper or hypoglycemia, glycosuria and possible osmotic diuresis, and cholestasis or steatosis (or both) as a result of long-term high-caloric intake. Intravenous lipid solutions provide 10 kcal/g. A 20% soybean emulsion is commonly used

**Figure 112-7** Olsen growth chart. (From Olsen IE et al. *New intrauterine growth curves based on United States data*. *Pediatrics*. 2010;125:e214.)

because it is more efficiently cleared than the 10% solution and provides 2 kcal/mL. Lipid infusions are administered over a 20- to 24-hour period at rate of 0.12 to 0.15 g/kg/hour and should not exceed 60% of the total caloric intake. Triglyceride levels should be measured periodically and should be less than 200 mg/dL. Potential adverse effects from lipid infusions include hyperlipidemia, bilirubin displacement

from albumin-binding sites by free fatty acids, potential to interfere with pulmonary clearance in infants with chronic lung disease, lipid overload resulting in hepatic failure, and coagulopathy. The ratio of calcium to phosphorous in PN solutions is 1.3 to 1.7:1 by weight.

Additional additives to PN solutions include trace elements and vitamins. Trace elements contain zinc,

**Table 112-3** Parenteral Nutrition Macronutrient Components

NUTRITIONAL GOALS FOR PARENTERAL NUTRITION	NONPROTEIN CALORIES (KCAL/KG/DAY)	CARBOHYDRATE (MG/KG/MIN)	PROTEIN (G/KG/DAY)	PROTEIN (G/KG/DAY)
Basal metabolic need (prevents catabolism)	50–60	4–6 (glucose infusion rate)	1.0–1.5	0.6–1.0 (prevents essential fatty acid deficiency; 4%–5% total fat calories should be from linoleic acid and 1% from linolenic acid)
Positive balance (promotes growth)	80–100	8–10; gradually advance to max 12–13	2.7–3.5	3.0–3.5 (30%–55% of the total calories from fat)

<sup>c</sup>Postoperative

<sup>d</sup>Calciuric diuretics

manganese, copper, and chromium, and are typically initiated 2 to 3 weeks after birth if the infant does not have renal or liver dysfunction. During the first 2 weeks of life, zinc should be provided in a dose of 0.15 mL/kg/day (150 mcg/kg/day; 1-mg/mL concentration). Thereafter, preterm infants require an additional 300 mcg/kg/day, and full-term infants should receive 200 mcg/kg/day of zinc. Selenium is also essential for both preterm and full-term infants and should be given in a dose of 2 mcg/kg/day. Trace elements are discontinued from the PN solution if the infant develops cholestasis. Trace element requirements are adjusted to provide a total daily intake of 400 mcg/kg/day of zinc for the preterm infant (100–350 mcg/kg/day for full-term infants), 0.2 mcg/kg/day of chromium, and 2 mcg/kg/day of selenium. Pediatric vitamins, 2 mL/kg/day, are also added to PN solutions up to a maximum of 5 mL/day. Heparin is often added to PN solutions to be administered through a central line.

Biochemical monitoring for infants on established (maintenance) PN regimens typically includes evaluation of blood electrolytes, blood urea nitrogen, creatinine, and calcium 1 to 3 times per week. Liver function studies (albumin, total and direct bilirubin, alanine aminotransferase,  $\gamma$ -glutamyltransferase, alkaline phosphatase), phosphorus, magnesium, triglyceride level, and complete blood count, including differential and platelet count, are monitored weekly to biweekly while the infant is receiving PN. Growth should be assessed weekly, plotting the occipitofrontal circumference, weight, and length on standard postnatal growth charts (Figure 112-5, Figure 112-6, Figure 112-7).

The baby is weaned from PN as advancing enteral feeding intake is tolerated. Once the daily enteral intake exceeds 50 mL/kg/day the lipid infusion can be discontinued. Thereafter, PN is typically stopped when the infant's intake is 80 to 120 mL/kg/day. The wide range in total enteral fluid intake at which PN may be discontinued relates to a lack of consensus on the optimal duration of PN support and the need to individualize therapy based on a baby's specific energy and nutrient needs. Infants who develop cholestasis and continue to require prolonged PN therapy benefit from *cycling* (intermittent infusion) of the PN solution with lipid administration limited to 3 days/week. Intermittent PN infusion promotes a feeding-fasting cycle that decreases the severity of cholestasis. If this strategy is used, then close monitoring of the infant's glucose is necessary to avoid hypoglycemia.

### Enteral Nutrition

Enteral feeding regimens typically begin with expressed breast milk or preterm formula. Infants may be nipple fed if they are clinically stable, with respiratory rates less than 60 to 70 breaths/min, and they are 34 weeks' gestation or older. Infants between 32 and 34 weeks' gestation may be able to nipple feed but should be assessed to document their oromotor skills, state regulation, and evidence of a coordinated suck-swallow-breathing pattern. Bolus feeding rather than continuous feeding is preferred for the recovering neonate.

### Feeding Intolerance

A common concern relates to the significance of gastric residual volumes and the risk for necrotizing enterocolitis. The color or volume (or both) of aspirated gastric residuals are factors often considered in the decision whether to continue enteral feeding. Investigators have shown that the color of the gastric residual did not predict the risk for developing necrotizing enterocolitis. Maximal residual volumes of more than 3.5 mL or greater than 33% of the feed volume are suggested as the threshold for concern that requires clinical assessment of the infant. However, an important point to note is that gastric residuals must be considered in the context of the infant's clinical status, vital signs, abdominal examination, stool character, and stooling pattern.

Premature infants are predisposed to feeding intolerance because of functional dysmotility and immaturity of the gastrointestinal tract, particularly after prolonged periods of no oral intake. Lack of early enteral feeding disrupts the intestine's barrier functions, which leads to gut atrophy, loss of intestinal villi and malabsorption, bacterial translocation, and impaired immune function. The initiation of early small-volume minimal enteral or trophic feedings is beneficial in maintaining intestinal integrity and promoting gastrointestinal motility.

Erythromycin has been recommended by some investigators for infants who are unable to establish full enteral feeding within 2 to 3 weeks of age. It has prokinetic properties as a motilin agonist that stimulates gastric emptying and proximal small intestinal contractility. Data from several randomized clinical trials provide conflicting results about the efficacy of erythromycin in improving feeding tolerance. Comparison of these studies is difficult because each employed a different erythromycin dose (low vs antimicrobial), route (enteral vs intravenous), and mode (prophylactic or rescue) of treatment. A 2008 meta-analysis by Ng and colleagues examined 10 randomized studies and found insufficient evidence to recommend the use of erythromycin in low or high doses for preterm infants with or at risk of feeding intolerance. However, the meta-analysis did identify evidence that use of erythromycin at higher treatment doses (40–50 mg/kg/day) or in infants older than 32 weeks GA reported more positive effects in improving feeding intolerance without higher complication rates of necrotizing enterocolitis or sepsis.

Given concerns regarding erythromycin-induced hypertrophic pyloric stenosis and cardiac arrest, prophylactic treatment of preterm infants is not routinely recommended. If a trial of erythromycin is used to promote intestinal motility, then the oral route is preferred because of the risk of significant morbidity and mortality with intravenous administration. The optimal and safest dose of erythromycin is not known. However, exposure to antimicrobial doses for more than 14 days has been associated with the development of hypertrophic pyloric stenosis. A 2005 review by Patole et al summarizes the current understanding of the physiological gastrointestinal function and feeding intolerance in premature infants and the gastrointestinal effects of erythromycin. Currently, erythromycin can

be cautiously recommended only for a select subset of premature infants older than 32 weeks GA with a protracted course of feeding intolerance.

### **Human Milk and Preterm Infant Formula Use**

Human milk is the choice for feeding full-term and preterm infants. However, for the very low-birth-weight premature infant, human milk requires fortification to provide nutrient intakes comparable to intrauterine accretion rates. Human-milk feeding has been shown to result in improved neurodevelopmental and cognitive outcomes and visual acuity among premature infants in comparison with their formula-fed counterparts. Fresh milk is preferred when available. (See Chapter 88, Breastfeeding the Newborn.) Routine screening cultures for evidence of bacterial contamination or heat treatment of the mother's own milk has not been shown to be necessary or cost effective. If a mother's own milk is not immediately available, then use of pasteurized donor human milk, if available, may be considered. Pasteurized donor human milk maintains most of the properties of fresh human milk (immunoglobulins, growth and developmental hormones, enzymes, anti-inflammatory factors), is sterile, and reduces necrotizing enterocolitis while improving feeding tolerance. Studies have shown that healthy preterm infants born less than 30 weeks' gestation are able to tolerate milk volumes of 150 to 200 mL/kg/day without adverse effects. Human milk-fed, extremely low-birth-weight infants require approximately 180 mL/kg/day to achieve adequate growth, nutrient retention, and nutritional status.

The nutrient composition of human milk varies because of the individual properties of expressed milk and changes that occur during collection, storage, and use. The energy and protein content of expressed human milk varies, as does the fat content. Human milk is not homogeneous; as the milk stands, the fat content separates. Much of the variation in the energy content of milk used is the result of differences in or losses of fat in unfortified milk. Although concentrations of protein, sodium, and zinc decline during the period of lactation, the nutrient needs of premature infants remain higher than those of full-term infants, even after the preterm infant reaches term postmenstrual age. This circumstance results in the need to fortify expressed human milk to compensate for the inadequate nutrient supply. Mineral content of calcium and phosphorus varies less during lactation but remains too low with respect to the premature infant's nutrient needs. Low calcium and phosphorus intake causes physiological changes that result in poor bone mineralization that may have long-term effects on the preterm child's height. Nutrient availability of vitamin C, vitamin A, and riboflavin declines during collection, storage, and administration of expressed milk.

Human-milk fortification is typically started when the intake reaches 50 to 80 mL/kg/day. Additional caution is warranted for preterm infants who are significantly growth restricted at birth with evidence of absent or reversed end diastolic doppler flow on antenatal testing because of the risk for necrotizing enterocolitis in the population of infants. Fortification for this group of babies has been recommended to be delayed until the infant is tolerating at least 120 to 150 mL/kg/day unfortified

breast milk. Fortifiers typically provide 4 kcal/packet and are added to 25 mL of breast milk to achieve a caloric density of 80 kcal/dL (24 kcal/oz). Human milk fortifiers are available as a powder, an acidified liquid, and human milk-based products that support trophic feedings, pasteurized donor milk, and human milk fortifier to enrich breast milk feedings of the mother's own milk (Prolacta). Concerns about contamination and risk for sepsis from human milk mixed with powdered fortifier as well as insufficient protein intake from unmodified human milk have resulted in the development of liquid human milk fortifier and a hydrolyzed liquid protein fortifier. Additional calories may be required because poor weight gain (600–800 IU/L) and radiographic evidence of metabolic bone disease require increased calcium and phosphorus intake. Infants receiving more than 150 mL/kg/day of fortified human milk are at a greater risk for hypercalcemia and hyperphosphatemia and thus require closer monitoring of calcium and phosphorus levels. Preterm liquid formula may also be added to human milk to increase the caloric and nutrient intake.

*The Food and Drug Administration has issued a warning against the use of gum xanthum thickeners such as Simply Thick in preterm infant feedings, because this has been linked to an increased risk of necrotizing enterocolitis.*

Premature infant formulas are typically recommended for preterm infants weighing less than 1,800 g at birth or who are less than 34 weeks' gestation. Preterm formulas are cow milk-based, whey-predominant formulas that provide between 2.7 and 3.0 g of protein per 100 kcal. High-protein, higher-calorie preterm formulas that provide 3.3 g protein/100 kcal and 24 cal/oz are available for feeding growing low-birth-weight infants and premature infants who may need extra protein to help support growth. Studies have shown that the growth of hospitalized infants is related to protein intake. Extremely preterm infants, less than 28 weeks' gestation, have higher protein requirements than more moderate and later preterm infants. To meet the higher protein needs of this group of infants who are receiving expressed breast milk (their mother's milk or donor breast milk), liquid protein supplements are available. Fat calories are derived from long- and medium-chain triglycerides. A 30 cal/oz iron-fortified formula may be used for feeding growing low-birth-weight infants and premature infants with limited fluid intake because of the need for fluid restriction and/or higher caloric needs. This formula is also suitable for use as a human milk fortifier and/or a breast milk extender when mixed 1:1 with human milk. An important consideration when fortifying or modifying breast milk or an infant formula is assuring that the feeding is not hyperosmolar. The American Academy of Pediatrics (AAP) Committee on Nutrition recommends limiting the osmolality of nutrient dense feedings to less than 450 mOsm/L (see Table 112-6).

Formulas designed for preterm infants (Table 112-7) should be used instead of protein hydrolysate (Alimentum, Pregestimil, Nutramigen) or amino acid-based (Neocate, Elecare) formulas that are designed for full-term infants, unless a specific indication exists for use of one of these formulas (cholestasis, malabsorption, intestinal failure, or short-bowel syndrome). Soy

protein-based formulas are not recommended for pre-term infants who weigh less than 1,800 g because their use results in reduced serum phosphorus levels that contribute to reduced bone mineral content. In addition, use of soy protein-based formulas leads to poorer growth (weight and length) and lower serum albumin levels and poses the potential for aluminum toxicity.

Routine iron supplementation should begin at 2 months postnatal age providing 2 to 4 mg/kg/day of iron. Infants with iron deficiency anemia require a higher iron intake of 4 to 6 mg/kg/day. Oral vitamin supplements are initiated after 2 weeks of age, typically once the preterm neonate is able to tolerate full enteral feedings. A summary of nutrient recommendations for preterm and term infants is found in Table 112-7.

### Infants With Chronic Lung Disease

Nutrition management of infants with chronic lung disease includes providing appropriate nutrient and caloric intake to meet the infant's increased energy and nutrient needs. Babies with chronic lung disease have reduced fat accretion, fat mass, growth, and muscle mass. Infants with BPD continue to exhibit slow or faltering growth during the first year of life. Medication use can alter energy requirements because methylxanthines will increase energy expenditure, and dexamethasone therapy has been associated with decreased weight gain. Infants with BPD require 15% to 25% more calories per day (140–150 kcal/kg/day) during the acute phases of their disease compared with their healthy peers. Protein intakes of 3.5 to 4.0 g/kg/day are considered adequate to meet the anabolic and tissue growth requirements. Diuretic use is common in the management of infants with BPD, with resultant

increased urinary losses of sodium, potassium, chloride, and calcium. Replacement of excess salt and mineral losses is often required. Close monitoring of the electrolyte and mineral balance is important to prevent complications related to nutrient depletion and poor growth. Inadequate mineral intake combined with diuretic use increases the risk for osteopenia and metabolic bone disease (nutritional rickets). This risk may be further increased by using hydrolyzed, elemental formulas or preterm formulas that are modified by the addition of carbohydrate or fat but contain insufficient calcium and phosphorus for bone mineralization.

### Infants With Complex Congenital Heart Disease

Similar to infants with chronic lung disease, the caloric requirements for infants with complex congenital heart disease may be as high as 150 mL/kg/day. Adequate weight gain and growth may be impeded by episodes of hypoxemia, tachypnea, and feeding fatigue that limit intake and increase energy expenditure. Gastroesophageal reflux and delayed gastric emptying further complicate appropriate nutritional management. Poor nutrition contributes to delayed wound healing, impaired immunity, and an increased risk for infection. Swallowing difficulties are a common complication after cardiac surgery in children. Prolonged intubation and injury to the recurrent laryngeal nerve resulting in vocal cord paralysis also contribute to feeding difficulty. Fiberoptic endoscopic evaluation of swallowing is a useful adjunct in the assessment of feeding in these babies in order to construct an appropriate feeding regimen (gavage vs nipple) and plan for oral-motor therapy. Refer to Chapter 116, Health and Developmental

Similac Special Care 24 High Protein	Abbott Nutrition		24 cal/fl oz iron-fortified feeding for growing, low-birth-weight infants and premature infants who may need extra protein to help support growth Can be mixed with human milk or other preterm infant formulas for a variety of high-caloric, nutrient-dense formulas Not intended for feeding low-birth-weight infants after they reach a weight of 3,600 g (~8 lb)
Similac Special Care 30 with Iron	Abbott Nutrition	Available as ready-to-feed Can be mixed with other preterm infant formulas to achieve caloric densities of 26 and 28 cal/oz	Calcium and phosphorus ratio (1.8:1) Approximately 2 mg iron/kg body weight per day, when fed at 120 cal/kg/day Not intended for feeding low-birth-weight infants after they reach 3,600 g (~8 lb)
<b>SUPPLEMENTS</b>			
MCT oil	Mead Johnson/Novartis	Provides 8.8 kcal/mL; add 0.5 mL/oz of breast milk or formula	Can cause loose stools, steatorrhea; does not provide essential fatty acids
Safflower oil	—	Provides 8 kcal/mL	—
Microlipid emulsified safflower oil	Mead Johnson	Provides 4.5 kcal/mL	Contains long-chain fatty acids
Polycose glucose polymer (liquid or powder)	Abbott Nutrition	½ tsp of powder provides 4 kcal; 1 mL of liquid provides 2 kcal; 23 kcal/tbsp; add ½ tsp/oz of formula	Can cause diarrhea
Moducal	Mead Johnson	30 kcal/tbsp	
<b>SPECIALIZED FORMULAS NOT RECOMMENDED FOR ROUTINE USE</b>			
Soy-based formulas			Not recommended for infants with low birth weights Suboptimal carbohydrate and mineral absorption; results in less weight gain and linear growth, lower serum albumin and phosphorus levels, and higher alkaline phosphorus levels indicative of poorer bone mineralization No data to support the use of thickened formula in preterm infants with reflux after discharge
Enfamil AR (standard infant formula with added rice starch recommended for infant feeding of babies with gastroesophageal reflux)	Mead Johnson		
EleCare	Abbott Labs	1 scoop (9.4 g) added to 2 oz water provides 20 cal/oz	Amino acid–based infant formula with iron for use in infants with protein maldigestion, malabsorption, short-bowel syndrome, GI-tract dysfunction Fat blend contains 33% medium-chain triglycerides Does not contain milk protein, soy protein, fructose, galactose, lactose, or gluten
Pregestimil	Mead Johnson	1 packed scoop (8.9 g) added to 2 oz water provides 20 cal/oz	Hypoallergenic, lactose-free infant formula for babies with fat malabsorption problems
Neocate	Nutricia North America	1 scoop per oz water	55% fat as medium-chain triglycerides 100% free amino acids For use in infants with short bowel syndrome, multiple-food protein intolerance

FORTIFIER, FORMULA, SUPPLEMENT	MANUFACTURER	MEASURING	PRECAUTIONS, COMMENTS
Thickeners (rice cereal, carob)	—	A practice used by some physicians in the treatment of infants with symptomatic reflux or feeding problems assessed by a feeding therapist is to thicken infant formula with rice cereal	Thickening feedings is a common practice but is controversial. FDA warns against use of <i>Simply Thick</i> . Thickening human milk is often unsuccessful as the naturally occurring enzymes digest the thickener. Does not contain necessary vitamin and mineral content for the growing preterm infant. Some evidence that thickened feeds increase the duration of reflux episodes. For infants with feeding difficulties, thickened feedings may further exacerbate pre-existing feeding difficulties.

## GASTROESOPHAGEAL REFLUX AND GASTROESOPHAGEAL REFLUX DISEASE

GER, defined as the retrograde passage of gastric contents into the esophagus, occurs in approximately 50% of all young infants. Babies who exhibit symptoms or complications of GER (vomiting, poor weight gain, difficulty feeding, hematemesis, and airway symptoms such as chronic lung disease and airway inflammation, apnea, aspiration, and recurrent pneumonia) are classified as having gastroesophageal reflux disease (GERD), requiring evaluation and treatment. Therapy is empiric, with little evidence for efficacy of current treatment modalities. Pediatric clinical practice guidelines published in 2001 by the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and endorsed by the AAP list the following points:

- A time-limited trial of medical therapy for infants with symptomatic GER should be provided.
- An up to 4-week trial of a hydrolyzed or amino acid formula in infants with vomiting that is suspected to be caused by cow-milk allergy should be considered.
- Thickened feedings reduce visible vomiting but do not improve reflux.
- Antireflux formulas are not appropriate for preterm infants.
- Ensure adequate caloric intake; increase caloric density if necessary.
- Prone positioning may be beneficial for select infants with significant symptoms; however, supine sleep position is associated with the lowest risk of sudden infant death syndrome, and is the position of preference while the infant is convalescing in the neonatal unit and after discharge home.

- Infants who are maintained in the prone position require continuous monitoring.

Joint evidence-based recommendations from NASPGHAN and the European Society for Pediatric Gastroenterology, Hepatology and Nutrition published in 2009 provide a synthesis of the mechanisms involved in reflux and detail clinical practice approaches based on presenting symptomatology and complicating sequelae. This consensus practice guideline offers limited guidance regarding practice approaches for preterm and very young infants, although it does provide a review of the available evidence about pathogenesis and diagnostic and treatment modalities.

GER is common among preterm infants, who may exhibit 3 to 5 episodes of reflux per hour, and is related to physiological transient lower esophageal sphincter relaxation (TLESR). These episodes of TLESR occur in both asymptomatic and symptomatic infants and may be elicited by gastric distention that accompanies feeding and abdominothoracic straining that accompanies movement. Episodes of acid GER have been shown to occur frequently in healthy preterm infants and resolve in most preterm babies as they reach term postmenstrual age. Use of gavage feeding tubes is also associated with increased reflux symptoms. Clinical concerns about feeding intolerance and recurrent episodes of apnea, bradycardia, and desaturation lead to the frequent use of prokinetic agents and acid suppressant drugs. However, behaviors often interpreted as signs of reflux disease in the preterm infant are nonspecific and not predictive of esophagitis. In addition, although reflux episodes may be more common in infants with BPD, there is no evidence that GERD therapy affects the clinical course or outcome.

The frequency of feeding in young infants results in relatively brief periods of gastric pH less than 4; consequently, pH probe measurements may not be helpful in

diagnosing significant reflux in the preterm infant. Although a common concern is that GER may contribute to apnea, numerous studies have failed to document a link between the 2 events. Impedance studies have demonstrated retrograde reflux of air and fluid into the esophagus occurring in addition to episodes of acid reflux. Approximately 25% of reflux events are strongly acidic, with total esophageal exposure time to acid estimated to be 5%. Recent studies have not confirmed a temporal link between acid-based GER and AOP. As a result, medication use to treat reflux is not recommended as part of the management of episodic apnea, bradycardia, and desaturation in preterm infants. Other pharmacologic and medical approaches may be necessary to optimize growth, nutrition, and respiratory function. The challenge that arises in management of GER in the preterm infant is the lack of data on the efficacy of antireflux measures. Although metoclopramide has been shown to reduce reflux symptoms, its use is associated with adverse effects such as irritability, dystonic reactions, drowsiness, emesis, apnea, and involuntary muscle movements, as well as oculogyric crisis (involuntary upward conjugate gaze). Metoclopramide's action as a dopamine-receptor antagonist accounts for its promotility effects in the intestine and blockade of dopamine receptors in the brain, resulting in the central nervous system effects. Therefore, metoclopramide is not recommended in the management of reflux in preterm and young infants.

Symptomatic preterm infants with GERD often exhibit significant vomiting of more than 50% of the fed volume more than 3 to 4 times per day in conjunction with:

- Recurrent episodes of apnea, bradycardia, and desaturations associated with feeding
  - Signs of discomfort or distress during feeds (arching, crying)
  - Difficulty advancing feeding volume
  - Poor weight gain
- Management strategies include:
- Infant positioning in prone with slight elevation of the head of the bed (requires continuous monitoring)
  - Infant transitioned to supine sleep position 1 to 2 weeks before anticipated discharge home to lessen the risk for sudden infant death syndrome
  - Consideration of discontinuation of methylxanthines (caffeine or theophylline)
  - Symptoms of infant reflux are rarely so severe that breastfeeding should be discontinued
  - Breastfeeding infants with regurgitation and vomiting may benefit from a 2–3 week trial of withdrawal of cow's milk products, beef, soy, and eggs from the maternal diet

Acid suppression therapy, although not well studied in the preterm infant, may also be considered: histamine-2 ( $H_2$ ) blockers (ranitidine [1 mg/kg/dose every 12 hr], famotidine [1 mg/kg/day divided every 12 hr]) or proton pump inhibitors (omeprazole [1.0 mg/kg/day given once daily or divided every 12 hours] or lansoprazole [1.5 mg/kg/day given once daily or divided every 12 hours]). Care must be taken if  $H_2$ -blockers are used because therapy has been associated with higher rates of necrotizing enterocolitis in very low-birth-weight infants. Famotidine has been shown to decrease the

number of reflux episodes and crying time in infants between 1 and 11 months of age, but treatment was also associated with increased neurologic events, including increased irritability, anorexia, and somnolence. Orenstein et al determined in a multicentered randomized clinic trial that there was no difference in efficacy between lansoprazole and placebo for symptoms attributed to GERD in infants age 1 to 12 months. Severe adverse events, particularly lower respiratory tract infections, occurred more often with lansoprazole than with placebo. Consultation with a pediatric gastroenterologist may be considered. It is well recognized that pediatric subspecialists such as gastroenterologists and pulmonologists more frequently prescribe  $H_2$  blockers and PPI medications than their neonatologist colleagues. A recent review by Shakhnovich and colleagues suggests that for a subset of infants with acid reflux, PPI medications may be beneficial.

If a family history of allergy exists, then the physician should consider having the mother eliminate dairy from her diet if she is providing breast milk for the infant, or initiate a trial of an elemental (casein-hydrolyzate) formula such as Pregestimil, Alimentum, or Nutramigen. Neocate or EleCare (amino acid–based formulas) may be used for infants with severe milk intolerance. (For a full discussion of the management of GERD, see Chapter 255, Gastroesophageal Reflux Disease.)

## CHOLESTASIS

Parenteral nutrition–associated cholestasis (PNAC), or parenteral nutrition–associated liver disease (PNALD), is a complication seen among infants who have enteral feedings withheld for extended periods. At greatest risk are infants with intestinal immaturity or intrinsic gastrointestinal disease, sepsis, and hypoxemia, and babies who require prolonged PN. Among preterm infants, babies at less than 28 weeks' gestation and infants who are small for GA are at greater risk of developing PNAC. The time to full enteral feeding has been shown to be a significant predictor of PNAC; rates of PNAC are higher among infants with chronic lung disease (BPD). Toxicity has been associated with amino acids such as methionine; trace elements such as copper, chromium, and manganese; intravenous soy-derived lipid infusions (providing primarily omega-6 fatty acids), and excessive energy and dextrose intakes. Medications and nutrient deficiencies of taurine, cysteine, choline, fatty acids, and trace minerals have been associated with an increased incidence of cholestasis. Biochemical abnormalities include elevations in serum alkaline phosphatase, direct bilirubin, and transaminases. Direct bilirubin levels above 2 to 3 mg/dL warrant evaluation and intervention. Treatment strategies include small amounts (trophic) of enteral feedings, especially for infants who require PN for longer than 3 weeks because enteral feeding enhances gastric motility and bile flow. Trace minerals (copper and manganese) can be eliminated from PN once enteral feeding is initiated. Cycling of PN is also suggested for infants who may require long-term PN once they are more than 44 to 48 weeks PMA. Intravenous lipid emulsion infusions are typically reduced to 1 g/kg/day on alternating days or 2 to 3 times per week while the infant remains PN dependent. Cholagogues such as ursodeoxycholate (Ursodiol or Actigall, 10 mg/kg/dose

every 8–12 hours) are also used to treat cholestasis and are considered more efficacious than phenobarbital or amoxicillin. Discontinuation of PN and progression of enteral feedings result in a gradual improvement of cholestasis over weeks to months.

## OSTEOPENIA

Osteopenia of prematurity (OOP), also referred to as *nutritional rickets* or *metabolic bone disease of prematurity*, occurs frequently in very low-birth-weight infants who exhibit decreased bone mineral content because of inadequate mineral intake, prolonged PN use, and chronic diuretic therapy. Infants with enterostomies may also exhibit increased electrolyte and mineral losses from high ostomy output (Box 112-12). Medications commonly used in premature babies that result in calcium excretion and increase mineral needs include furosemide, xanthines, and dexamethasone. Anticonvulsants such as hydantoin and phenobarbital increase the turnover of vitamin D, leading to decreased serum levels of calcium and magnesium. Use of chronic thiazide diuretics also contributes to bone demineralization. Renal or liver disease increases the risk for osteopenia.

Mineral deficiencies are reported to occur in 30% to 50% of preterm infants who are fed either unfortified human milk or formulas designed for full-term infants. Infants born with very low birth weight or 28 weeks' gestation or less are at highest risk for OOP primarily as a result of inadequate phosphorus intake. Growing preterm infants who are fed human milk exclusively will not achieve bone mineral contents comparable to that attained through in utero accretion. Radiographs of the wrist and long bones reveal evidence of poor bone mineralization ("thinning"), with widening and cupping at the metaphyseal ends of the bones. Healing fractures may also be noted on routine radiographs involving the ribs and long bones. The risk for fractures is greatest between 6 and 12 weeks postnatal age; fractures occur in approximately 10% of very low-birth-weight infants and when alkaline phosphatase (APA) levels exceed 1,000 IU/L. Given that vitamin D deficiency is not a primary factor in OOP, supplemental vitamin D beyond nutritional requirements, 200 to 400 IU daily, is generally not needed unless serum 1, 25-OH vitamin D levels are low. Infants with cholestasis require additional vitamin D supplementation. Human milk should be fortified or the appropriate premature formula used. In the United States, fortification of human milk is recommended for very low-birth-weight preterm infants until a weight of 1,800 to 2,000 g is reached.

Routine monitoring of serum phosphorus and APA levels is helpful in detecting very low-birth-weight infants at risk for metabolic bone disease beginning at 4 to 6 weeks postnatal age and biweekly thereafter. Although serum calcium and APA levels are monitored in conjunction with serum phosphorus values, they are not useful markers of bone mineralization. In general, serum calcium remains within normal levels at the expense of bone loss. Alkaline phosphatase levels are elevated and serum phosphorus levels are lower in babies with osteopenia. Serum calcium levels are typically maintained within a normal range during osteopenia at the expense of bone mineralization. Serum APA levels greater than 800 to 1,000 IU/L in

### BOX 112-12 High-Risk Criteria for Rickets in Preterm Infants

- Born at <27 weeks' gestation
- Birth weight <1,000 g
- Long-term parenteral nutrition (eg, >4 to 5 weeks)
- Severe bronchopulmonary dysplasia with use of loop diuretics (eg, furosemide) and fluid restriction
- Long-term steroid use
- History of necrotizing enterocolitis
- Failure to tolerate formulas or human milk fortifiers with high mineral content

From Abrams S; American Academy of Pediatrics Committee on Nutrition. Clinical Report: Calcium and vitamin D requirements of enterally fed preterm infants. *Pediatrics*. 2013; 131(5):e1676–e1683.

conjunction with a serum phosphorus concentration less than 4.0 mg/dL (1.3 mmol/L) warrant radiographic evaluation of the wrist or knee for evidence of rickets or severe bone loss. Physical activity in the form of passive range of motion exercise has been shown to reduce bone mineral losses, increase bone strength, and promote growth in preterm infants. Among very preterm infants who do not develop rickets, clinical experience indicates that if the infant has serum alkaline phosphorus levels less than 400 to 800 IU/L and has achieved full feeds of human milk with a mineral-containing fortifier or a preterm infant formula, there is minimal, if any, risk of developing rickets, and measurement of APA can usually be stopped. Treatment strategies for the management of the preterm infant with nutritional rickets are summarized in Box 112-13.

In preparation for discharge, very low-birth-weight/very preterm infants typically transition from high mineral containing fortified human milk or preterm formula to unfortified human milk or a postdischarge preterm formula. This process often begins when the infant achieves a body weight of 1,800 to 2,000 g. Delaying the switch to transitional/post-discharge preterm formulas and continuing the use of formula designed for preterm infants or human milk fortifier should be considered for infants on fluid restriction, especially less than 150 mL/kg per day, or for infants with a prolonged course of parenteral nutrition and a persistent elevation of serum APA (ie, >800 IU/L). Use of formula designed for preterm infants would likely be safe until body weight of at least 3,000 g is reached. Extended use of preterm formulas beyond this time may result in excessive vitamin and mineral intake. The AAP Committee on Nutrition recommends that preterm infants who do not tolerate cow-milk protein or lactose-containing products continue biochemical monitoring for an extended period of time, and in some cases that the infants receive direct supplementation with added minerals. Amino acid-based, soy-based, and other specialized infant formulas generally have higher levels of minerals than do routine infant formulas, but the bioavailability of these minerals, especially in high-risk

### BOX 112-13 Management Approach for Enterally Fed Preterm Infants With Radiologic Evidence of Rickets

1. Maximize nutrient intake. Consider increasing human milk fortifier and/or feeding volume of preterm formula, as clinically indicated. If unable to tolerate human milk fortifier or preterm formula, then will likely need elemental minerals added as described below.
2. If no further increases in these can be made, add elemental calcium and phosphorus—usually beginning at 20 mg/kg per day of elemental calcium and 10–20 mg/kg/day elemental phosphorus and increasing, as tolerated, usually to a maximum of 70–80 mg/kg per day of elemental calcium and 40–50 mg/kg/day elemental phosphorus.
3. Evaluate cholestasis and vitamin D status. May consider measuring 25-OH-D concentration, targeting serum 25-OH-D concentration of >20 ng/mL (50 nmol/L).
4. Follow serum phosphorus concentration and serum APA weekly or biweekly.
5. Recheck radiographs for evidence of rickets at 5- to 6-week intervals until resolved.
6. Advise caregiving team to be cautious in handling of infant.
7. Limit use of steroids and furosemide, as clinically feasible.

From Abrams S; American Academy of Pediatrics Committee on Nutrition. Clinical Report: calcium and vitamin D requirements of enterally fed preterm infants. *Pediatrics*. 2013; 131(5):e1676–e1683.

infants such as those with a history of feeding intolerance or intestinal failure, is uncertain.

## TRANSITION TO ORAL FEEDING

Feeding disorders are common among infants, particularly babies who have been ill or who are preterm. The ability to nipple feed is an important developmental task that requires neurologic maturation, self-regulation, motor strength, and physiological stability. Successful nipple feeding requires coordination of nutritive sucking, swallowing, and breathing. Coordination of the tongue, pharynx, and upper trunk movements is necessary for an infant to swallow safely. The infant must also learn to protect the airway during feeding. In preterm infants this process is complicated by the occurrence of *deglutition apnea* episodes in which the infant stops breathing during successive swallows while feeding. This occurrence diminishes as the infant matures and as feeding skill improves.

Oral feeding is not initiated in preterm infants before 32 weeks of PMA mainly because the coordination of sucking, swallowing, and respiration is not established. Significant maturation of feeding behaviors occurs between 33 and 36 weeks PMA with more coordinated suck-swallow-respiration patterns; longer sucking bursts are noted by 37 weeks PMA. By 35 weeks' gestation, swallowing occurs typically at the end of inspiration. Consequently, swallowing less frequently interrupts respiration.

### BOX 112-14 Techniques to Support Development of Oral Feeding Skills

- Nonnutritive sucking, offering the infant a pacifier or the infant's fingers to suck and orally explore:
  - Accelerates transition from tube to oral feedings
  - Enhances weight gain and increases gastrointestinal motility
  - Improves the infant's behavioral state and organization
  - Does not fully reflect the oral feeding experience because swallowing is less and rhythmic sucking and breathing can more easily occur
- Provide tastes of breast milk or formula on the pacifier or infant's fingers; provides sensory stimulation before the introduction of nipple feeding
- Kangaroo care allowing the infant to nuzzle, lick, and suck at the mother's breast
- Use of slower or low-flow nipples to support the infant's swallowing; bolus size will increase as the infant's feeding skills mature and coordination improves
- Jaw, cheek, and/or chin support and proper positioning to sustain postural control
- Pacing:
  - Useful for infants who are not yet able to self-regulate their feeding or control successive swallows
  - Done by shifting the infant slightly forward every 3 to 5 sucks or the bottle tilted down to allow the milk to drain from the nipple and giving the infant a chance to breathe
- Demand or "infant-driven" feeding rather than a set feeding schedule, such as every 3 hours
- Some infants will require supplemental oxygen during nipple feeding to maintain adequate oxygenation and prevent desaturations and bradycardic episodes
- Assessment and monitoring of the infant's coordination of the suck-swallow-breathing sequence is necessary for timely identification of feeding difficulties

Infants who are less mature at birth, who experience complex medical courses with significant respiratory illness, or who require prolonged ventilation or oxygen therapy have greater difficulty establishing nipple feeds and take longer to master coordination of sucking, swallowing, and breathing than their healthy counterparts. Infants who have difficulty coordinating sucking, swallowing, and breathing quickly fatigue and lose motor tone. This situation contributes to desaturation, apnea, and bradycardia while feeding. For many of these infants, feeding difficulties continue after discharge from the neonatal unit and throughout infancy. These feeding behaviors lead to the development of feeding refusal in some infants. Sensorimotor interventions that combine sucking and swallowing exercises (oral + tactile/kinaesthetic stimulation) have been shown to improve oral feeding in very preterm infants.

Techniques helpful in supporting the development of oral feeding skills are listed in Box 112-14.

### BOX 112-15 Assessment of an Infant's Oral Feeding Ability

Assessment of an infant's oral feeding ability encompasses the following:

1. State regulation and response to tactile stimulation
2. Feeding position
3. Oral motor control
4. Physiological response to feeding episode
5. Coordination of suck-swallow-breathing sequence
  - a. Consider feeding evaluation by a speech pathologist or feeding therapist
  - b. Consider airway and feeding efficiency assessment with a modified barium swallow and fiberoptic endoscopic swallowing study to evaluate the vocal cords and swallowing and assess for evidence of aspiration
6. Caregiver–infant feeding interactions

The first attempts at oral feeding usually occur between 32 and 33 weeks' GA or PMA and exhibits a stable respiratory status. Infants are deemed to be successfully nipple feeding when they are able to complete feedings within 20 minutes. This goal may or may not be fully achieved by the time of the infant's discharge home. The choice of nipple used may facilitate or impede feeding efficiency. Some infants benefit from use of low- or variable-flow nipples to aid pacing during the feeding. Infants who are unable to achieve full nipple feeding may require a specialized program of intensive feeding therapy. A gastrostomy may also need to be placed if the infant is unable to gain adequate weight until sufficient oral feeding is attained. Signs that an infant may not be developmentally ready to initiate nipple feeding include falling asleep, not latching on, or exhibiting respiratory irregularity and loss of muscle tone when a bottle is placed in the mouth.

Assessing an infant's oral feeding ability requires evaluating multiple considerations (Box 112-15). The physician plays a critical role in promoting breastfeeding of the hospitalized infant (Box 112-16, Box 112-17).

## HEALTH MAINTENANCE

### Newborn Screening of the Critically Ill or Premature Infant

Newborn screening is an important component of acute and continuing care for the sick or preterm infant. Maternal medical conditions and treatments can affect newborn screening results. In addition, prematurity, low birth weight, illness, and treatments received by infants requiring neonatal intensive or specialized care can also alter newborn screening results. Most neonatal units have established protocols that specify the timing when newborn metabolic screening is conducted for babies requiring specialized neonatal or intensive care or transfer to another hospital. State health department newborn screening policies guide individual hospital

### BOX 112-16 Promotion of Breastfeeding in the Hospitalized Infant

- Discuss feeding options for the infant and the benefits of providing colostrum or human milk
- Provide mother with information or handouts on human milk expression and storage
- Work with nursery and postpartum staff to ensure that human milk expression is initiated in the first hours after delivery, employing both hand expression and use of an electric breast pump
- Provide referral to lactation consultant (hospital or community-based)
- Facilitate arrangements to rent or purchase a hospital-grade electric breast pump to support mother's goal of providing expressed human milk for her infant
- Most state Medicaid departments and WIC programs have guidelines that authorize payment for hospital-grade electric breast pumps for infants with the following conditions:
  - Prematurity
  - Neurologic disorders
  - Genetic abnormalities (Down syndrome)
  - Anatomic and mechanical malformations (cleft lip and palate)
  - Congenital malformations requiring surgery
  - Prolonged infant hospitalization
  - Conditions that prevent normal breastfeeding (respiratory compromise)
- Many insurers will include among subscriber benefits (these are plan specific) recommendations for electric breast pump authorization, such as prematurity, feeding difficulty caused by abnormal infant suck, or a hospitalized mother or infant

WIC, Special Supplemental Nutrition Program for Women, Infants, and Children.

practices. The timing of the first newborn screen is typically between 24 and 48 hours of age after the infant has established milk (human milk or formula) feeding. The infant who requires transfer to another facility, needs a blood transfusion, or is critically ill should have a newborn screening test obtained on the first day of life (<24 hours of age). A second screening test should be obtained between 48 and 72 hours of age. Infants who are less than 34 weeks' gestation or less than 2,000 g at birth require a repeat blood spot screen at 28 days of age. However, if the infant has a short NICU stay and few treatments, the third screening sample may not be necessary. Repeat screening is required on any infant with abnormal results on a first screen. Box 112-18 summarizes the advantages and disadvantages of screening at different points.

If an infant is transfused before obtaining the initial newborn screening test, then an additional specimen is necessary 2 to 3 months posttransfusion or when the blood cells tested are presumed to be the infant's and not reflect those of the donor. Earlier retesting may reflect donor hemoglobins and invalidate testing for galactosemia (red blood cells assayed

**BOX 112-17 Transition to Breastfeeding**

- Criteria to initiate *nonnutritive sucking time at the breast*
  - Begin at approximately 30 to 32 weeks gestational or postmenstrual age
  - Infant demonstrates ability to swallow own secretions
  - Stable outside incubator for more than 10 to 15 minutes
  - Able to tolerate kangaroo care (skin-to-skin contact)
  - Infant responses:
    - Mouth is at the breast; may or may not latch on or suck
    - May swallow once or twice
    - May fall asleep at the breast
  - Coordinate nonnutritive nursing attempts with infant hunger cues
- Reinforce importance of expressing breast milk every 3 hours (100 min/day)
- Initiation of nutritive sucking:
  - Infant displays consistent latch-on ability
  - Infant is able to feed for approximately 5 minutes
  - Supplementation with expressed human milk or formula after nursing episode:
    - Breastfeeds
    - Breastfeeds 5 to 10 minutes: gavage one-half enteral feeding volume
    - Breastfeeds more than 10 minutes: supplementation is not needed unless inadequate weight gain or signs of dehydration are exhibited
- Mother should continue to pump between and after feedings in order to maintain her milk volume as the infant's nursing skills strengthen.

for galactose-1-phosphate uridylyltransferase). Infants receiving PN, particularly preterm infants, may have elevated amino acids (eg, phenylalanine) resulting in positive screening results.

Current newborn screening recommendations include testing for cystic fibrosis. Testing algorithms rely on immunoreactive trypsinogen (IRT) or screening for cystic fibrosis transmembrane conductance regulator mutations. Newborn infants with meconium ileus are at risk for cystic fibrosis but may have low initial IRT test results (false negative). Consequently, all babies with meconium ileus require follow-up sweat tests. Infants experiencing severe perinatal distress or who have low Apgar scores may exhibit elevated IRT levels on testing (false positive). Follow-up testing is needed.

Premature infants often have abnormal newborn screening test results that are not the result of an underlying metabolic disorder. Preterm infants often have elevated 17-hydroxyprogesterone (17-OHP) and low thyroxine levels. The typically higher 17-OHP level in premature infants presents a difficulty in diagnosing congenital adrenal hyperplasia among this group of babies. Many states use weight-adjusted cutoff values to reduce the high false-positive rates seen with standard testing. Antenatal corticosteroid treatment does not seem to suppress 17-OHP levels. Transient hypothyroxinemia, with low thyroxine and normal

**BOX 112-18 Newborn Dried Blood Spot Screening****SCREEN UPON ADMISSION****Advantages:**

- Reliable for hemoglobinopathies (ie, sickle-cell anemia), galactosemia, and biotinidase deficiency
- Provides baseline amino acid and acylcarnitine levels
- May be more likely to detect fatty acid oxidation disorders caused by the infant's catabolic state
- Increases chance screening specimen will be drawn on every baby requiring neonatal specialized or intensive care

**Disadvantages:**

- Increased false positive and negative results for TSH (thyroid stimulating hormone)/17-OHP (17-hydroxyprogesterone) and IRT (immunoreactive trypsinogen, screens from CF, cystic fibrosis)
- Interpret abnormal results for CH, CAH, and CF with caution: many of these may normalize on a repeat screen

**SCREEN AT 48 TO 72 HOURS (IF FIRST ONE <24 HOURS)****Advantages:**

- Should be reliable for congenital hypothyroidism (CH, unless TSH primary), congenital adrenal hyperplasia (CAH), CF, and most aminoacidopathies (unless baby is receiving parenteral nutrition)
- 90% of first specimen abnormalities disappear

**Disadvantages:**

- Carnitine and fatty acid oxidation disorders may be masked if the infant is receiving adequate nutrition from parenteral nutrition
- Will not identify CH with delayed rise in TSH

**RESCREEN AT 28 DAYS OR UPON DISCHARGE (WHICHEVER OCCURS FIRST)**

Infants <34 weeks, gestation or <2,000 g

**Advantages:**

- For especially small premature babies, thyroid function may have matured to expected newborn levels
- May resolve (for most) any previous abnormal results such as multiple amino acids or carnitine elevations
- Especially beneficial for very low-birth-weight babies likely to have had more interventions that interfere with NBS results

**Disadvantages:**

- Cost of additional screening

thyroid-stimulating hormone levels, is common among sick preterm babies and is most often self-limited. Acute illness may further depress thyroid function and increase adrenal steroid production, contributing to persistent abnormalities on retesting. Preterm infants need to be monitored until normal test results are achieved. Infants with persistent abnormalities require assessment of thyroid function and may need treatment to reduce the risk of poor neurocognitive outcome related to hypothyroidism. Serial screening tests or diagnostic evaluation may be required based on local state health department requirements. Infants

with physical or metabolic signs suggestive of the condition should undergo an immediate evaluation for the suspected disorder.

### Cranial Ultrasonography Screening

In a preterm infant, limited cerebral autoregulation in association with vascular, cellular, and anatomic features of the developing brain result in vulnerability to hemorrhage and ischemic brain injury. Hemorrhagic lesions involve the germinal matrix (GM), and may extend into the ventricular system or be associated with parenchymal lesions in the brain. The GM involutes during the third trimester, by 34 to 36 weeks' PMA. Ischemic injury within the periventricular area is the injury pattern seen more commonly in less mature infants and is related to hypoperfusion and ischemia occurring along the end-zone regions of the long penetrating arteries that arise from the anterior, middle, and posterior cerebral arteries. Both hemorrhage and ischemic injury may occur coincidentally. White-matter injury may lead to nonhemorrhagic cerebral infarction, periventricular leukomalacia (PVL), or porencephaly. Ventriculomegaly (VM) may also occur because of loss of cerebral white matter in the absence of an intraventricular hemorrhage (IVH). Most IVH is evident by 3 days of age; 50% of hemorrhages occur within the initial hours following birth.

The American Academy of Neurology practice parameter on neuroimaging of the neonate recommends routine screening cranial ultrasonography in preterm infants between 7 and 14 days of age on all infants younger than 30 weeks' gestation. The initial study identifies IVH. The presence of cystic PVL within the first 2 weeks of age indicates an antenatal insult. A repeat study should be obtained between 36 and 40 weeks PMA to detect the presence of PVL and low-pressure VM. These 2 timeframes have been chosen as the most useful in terms of predicting long-term neurodevelopmental outcomes. However, from a clinical care perspective, diagnosing the GM hemorrhage or IVH early is often important. The Canadian Paediatric Society statement on routine screening cranial ultrasonography suggests that an earlier neurosonogram should be performed by the third day of life in infants with multiple early complications.

Follow-up studies should be obtained as clinically indicated. Because of the inverse relationship between brain injury and gestational age, an alternate approach has been suggested by Perlman and Rollins, who recommend an initial cranial sonogram between days 3 and 5 with 3 follow-up studies at 10 to 14 days of age, at 28 days of age, and before discharge for babies weighing less than 1,000 g at birth. The initial study at 3 to 5 days will identify 75% of hemorrhages in the extremely low-birth-weight preterm infant. The second ultrasound at 10 to 14 days of age will identify 84% of hemorrhages and detect early hydrocephalus and cyst formation. The 28-day scan identifies the presence of periventricular echogenicity and VM. The yield of these studies performed in more mature preterm infants decreases with increasing GA. Consequently the recommended periodicity for cranial ultrasonography screening in larger preterm infants is consistent with American Academy of Neurology

and the Canadian Paediatric Society guidelines. Although the American Academy of Neurology did not find sufficient evidence to recommend inclusion of conventional magnetic resonance imaging (MRI) of the brain at term postmenstrual age in addition to cranial sonography to assist in the prediction of neurodevelopmental outcome, recent research has increased understanding of the utility of this imaging technique in outcome prediction.

For full-term infants who exhibit neonatal encephalopathy with a history of birth trauma, low hematocrit, or coagulopathy, recommendations call for a noncontrast computed tomography (CT) scan to be performed. Infants whose CT scan is inconclusive should have an MRI performed between 2 and 8 days of age to assess the location and extent of the injury, information important in diagnosis and prognosis for the infant.

### Retinopathy of Prematurity Screening

ROP affects primarily premature infants weighing less than 1,500 g or who are born before 31 weeks' gestation. The incidence of ROP is inversely related to GA. ROP typically involves both eyes, is one of the most common causes of visual loss in childhood, and can lead to lifelong vision impairment and blindness. ROP is classified according to the severity of the changes in the developing blood vessels and the region of the retina into which these abnormal vessels have grown. The severity is referred to as the *stage* and the retinal regions as *zones* (Figure 112-8). Fifty percent of infants weighing 1,500 g or less at birth will develop some degree of ROP. For most preterm infants, ROP will regress as the infant matures. Approximately 10% of infants with ROP require medical treatment. Approximately 400 to 600 infants with ROP are classified as legally blind each year in the United States. Early treatment of severe ROP is important, producing significant reductions in unfavorable outcomes (retinal detachment, blindness, poor visual acuity).

Infants who are transferred back to the community hospital setting have been shown to be more likely to miss follow-up ophthalmologic care than infants remaining in tertiary care facilities. Infants not screened for ROP during their NICU hospitalization were more

**Figure 112-8** Retinopathy of prematurity is described by the examining ophthalmologist in terms of zones and stages, whereby the zone is the location of the retinopathy and the stage is the severity.

likely to miss follow-up care than infants assessed before hospital discharge. This tendency reinforces the need for communication between medical care providers and for written recommendations in transfer summaries that detail findings on the initial examinations (stage of ROP if present and zone to which the retina is vascularized) and specify the timing for subsequent follow-up evaluations.

The joint statement from the AAP, American Academy of Ophthalmology, American Association for Pediatric Ophthalmology and Strabismus, and American Association of Certified Orthoptists entitled “Screening Examination of Premature Infants for Retinopathy of Prematurity” and the Canadian Paediatric Society policy statement “Retinopathy of Prematurity: Recommendations for Screening” provide guidelines for the timing of the initial and follow-up eye examinations and offer criteria to determine the need for treatment.

#### Who should be screened?

- Infants with a birth weight less than 1,500 g or who are 30 weeks’ gestation or younger
- Selected infants with a birth weight between 1,500 and 2,000 g or gestational age greater than 30 weeks who have experienced an unstable clinical course, including the need for cardiorespiratory support, or who are thought to be at high risk

Table 112-8 provides the appropriate timing of the first eye examination in these infants. The following schedule of follow-up examinations is recommended based on the examining ophthalmologist’s findings:

- **1-week or less follow-up for:**
  - Immature vascularization: zone I—no ROP
  - Immature retina extends into posterior zone II, near the boundary of zone I
  - Stage 1 or 2 ROP: zone I
  - Stage 3 ROP: zone II
  - Presence or suspected presence of aggressive posterior ROP
- **1- to 2-week follow-up for:**
  - Immature vascularization: posterior zone II
  - Stage 2 ROP: zone II
  - Regressing ROP: zone I

#### 2-week follow-up for:

- Stage 1 ROP: zone II
- Immature vascularization: zone II—no ROP
- Regressing ROP: zone II

#### 2- to 3-week follow-up for:

- Stage 1 or 2 ROP: zone III
- Regressing ROP: zone III

The presence of plus disease (dilated, tortuous posterior retinal blood vessels) in zones I or II suggests that peripheral ablation, rather than observation, is necessary. Treatment may also be initiated for any of the following retinal findings:

- Zone I ROP: any stage with plus disease
- Zone I ROP: stage 3 with no plus disease
- Zone II: stage 2 or 3 with plus disease

Treatment should generally be accomplished, when possible, within 72 hours of determination of treatable disease to minimize the risk of retinal detachment. The conclusion of acute retinal screening examinations should be based on age and retinal ophthalmoscopic findings (see Figure 112-8).

The following medications are used to dilate the infant’s eyes: amethocaine 1% (or benoxinate 0.4%), cyclopentolate 0.5% (Cyclogyl), and phenylephrine 2.5%. One drop of each preparation is instilled in each eye 30 minutes before the ophthalmologist’s arrival (ie, 0800 hr for a 0830-hr starting time) and repeated 10 minutes later. The eye drops are effective for up to 2 hours from the last installation. Infants with a darker iris may require a longer time and repeat drops for their pupils to dilate. A sucrose nipple can also be used for analgesia during the eye examination.

#### Immunizations

Diphtheria-tetanus-acellular pertussis (DTaP), inactivated polio vaccine (IPV), *Haemophilus influenza* type b conjugate (HiB), and pneumococcal conjugate vaccines are recommended. Current AAP recommendations include immunization of clinically stable premature and low-birth-weight infants at 2 months postnatal age. Vaccines should be preferentially administered in the anterolateral area of the thigh using a small needle.

**Table 112-8** Timing of First Eye Examination Based on Gestational Age at Birth

GESTATIONAL AGE AT BIRTH (IN WEEKS)	AGE AT INITIAL EXAMINATION (IN WEEKS)	
	POSTMENSTRUAL	CHRONOLOGIC
22 <sup>a</sup>	31	9
23 <sup>a</sup>	31	8
24	31	7
25	31	6
26	31	5
27	31	4
28	32	4
29 <sup>b</sup>	33	4
30 <sup>b</sup>	34	4
Older gestational age, high risk factors		4

<sup>a</sup>Guideline should be considered tentative rather than evidence-based for infants 22–23 weeks gestational age

<sup>b</sup>If necessary

From American Academy of Pediatrics Section on Ophthalmology, American Academy of Ophthalmology, American Association for Pediatrics Ophthalmology and Strabismus. Policy Statement: Screening Examination of Premature Infants for Retinopathy of Prematurity. *Pediatrics*. 2013;131:189–195.

The immune responses in preterm infants to diphtheria, pertussis, and polio antigens are similar to those seen with full-term babies. In contrast, the immunogenicity of HiB vaccine varies and is thought to be altered by the choice of conjugate protein, use of combination vaccine, and the infant's underlying medical condition. Antibody responses to vaccines in low-birth-weight and preterm infants are often less than those in term infants, though protective antibody levels are achieved. Reports of adverse side effects after immunization of sick preterm infants have noted an increase in the incidence of apnea and cardiorespiratory events after the first vaccinations. These events are most common among infants with preexisting apneas, bradycardias, and desaturations at the time of DTaP-IPV-HiB immunization, some of whom may require intervention. However, concerns about potential cardiorespiratory events should not preclude timely immunization. Infants at risk should be appropriately monitored after vaccination.

### **Hepatitis B Vaccine**

The timing of the initial hepatitis B vaccine administration in preterm and low-birth-weight infants is based on birth weight and maternal hepatitis B surface antigen (HBsAg) status, given that immunogenicity is poor in newborns weighing less than 2,000 g when hepatitis B vaccine is given at birth. Infants born weighing less than 2,000 g to HBsAg-negative mothers should receive hepatitis B vaccine at 30 days of age or at the time of hospital discharge if this occurs before 30 days. If the mother's hepatitis B status is not known at the time of delivery, then hepatitis B vaccine should be given within 12 hours of birth. Hepatitis B immune globulin should also be administered within 12 hours for newborns weighing less than 2,000 g and within 7 days if the newborn is greater than 2,000 g and the mother is confirmed HBsAg positive.

### **Influenza Vaccine**

Rarely, a chronically ill infant may require continued hospitalization at 6 months of age. The first of 2 doses of inactive influenza vaccine should be administered at 6 months postnatal age, particularly for infants with chronic lung disease. It is important to encourage families to immunize all household contacts and caregivers if the infant is less than 6 months of age. In 2009, New York State passed legislation requiring that hospitals with a NICU offer flu vaccine to the parents and anticipated caregivers of newborns currently in the NICU during the flu season.

### **Rotavirus Vaccine**

The AAP recommends routine immunization of infants with either RV1 (live, oral human attenuated rotavirus vaccine) or RV5 (live, oral human-bovine reassortant rotavirus vaccine). If RV5 is used, it should be administered orally in a 3-dose series at 2, 4, and 6 months of age. If RV1 is used, it should be given orally in a 2-dose series at 2 and 4 months of age. Rotavirus vaccine may be administered to infants with minor acute illness. Current recommendations include administration of

the first dose of rotavirus vaccine between 6 weeks and 14 weeks, 6 days of age.

Preterm infants should be immunized on the same schedule and with the same precautions as term infants if they are clinically stable and meet the age requirements for rotavirus vaccine (6 weeks to 14 weeks and 6 days of age for the first dose). Because vaccine strains of rotavirus are shed in the stools of immunized infants, preterm infants in NICUs or nurseries who are age-eligible and clinically stable may be immunized at the time of discharge. If an immunized preterm infant is readmitted to the NICU within 2 weeks after vaccine administration, contact precautions should be instituted and maintained for 2 to 3 weeks after vaccine administration.

### **In-Hospital Respiratory Syncytial Virus Prophylaxis With Palivizumab**

Respiratory syncytial virus (RSV) is responsible for a significant percentage of lower respiratory tract infections (bronchiolitis and pneumonia) in young children. Immune prophylaxis is recommended for high-risk very preterm infants, preterm babies <32 weeks, 0 days' gestation with chronic lung disease (defined as oxygen requirement for at least 28 days after birth), infants <12 months of age with hemodynamically significant respiratory compromise affecting the infant's ability to clear secretions, or infants <24 months of age with profound immunocompromise. The physician should be familiar with local and regional variations in the onset and duration of RSV activity because these variations will guide when RSV immune prophylaxis should be initiated. Data from the Centers for Disease Control and Prevention National Respiratory and Enteric Virus Surveillance System suggest that the annual seasonal peak for RSV infection begins in July in Florida, in the remainder of the South in October, and in the Northeast during November. Highest RSV activity is in October, late December, and early January in Florida, the remainder of the South, and in the Northeast, respectively. Seasonal duration varies across the US from 13 weeks in the New England States (HHS region 1) to 27 weeks in Florida (HHS region 4; however the seasonal duration in the other states comprising region 4 is 22 weeks).

Family-centered care is integral to the functioning of most neonatal units nationwide. Siblings, parents, and grandparents, as well as various health professionals, are in contact with vulnerable infants, thus posing frequent potential infectious exposures including to RSV. Consequently, some physicians have advocated RSV immune prophylaxis with palivizumab in preterm infants hospitalized during RSV season. Studies have demonstrated that extremely preterm infants younger than 29 weeks PMA are able to mount a protective immune response to 15 mg/kg of palivizumab. Seventy percent of infants studied were able to maintain protective palivizumab concentrations 2 weeks after the initial dose. Less than 25% of infants maintained protective concentrations at 4 weeks after administration. Mid-point concentrations (2 weeks after prophylaxis) were higher after second and third palivizumab doses among the hospitalized cohort of infants. These findings have

been confirmed by other investigators. Palivizumab prophylaxis is not recommended for prevention of RSV nosocomial disease.

### Positional Plagiocephaly

Positional or deformational plagiocephaly is common among sick and preterm infants or may result from positioning in a restrictive uterine environment. The calvarial bones of the cranium are more malleable in the preterm infant than in their healthy peers, increasing the infant's susceptibility to external molding forces. This circumstance results in unilateral flattening in the parieto-occipital region, with associated anterior advancement of the ipsilateral ear and anterior displacement (bossing) of the ipsilateral forehead. The head shape resembles a parallelogram. The weight of the infant's head and the child's overall decreased tone and strength are contributing factors as well. Preterm and sick infants, particularly those who require prolonged ventilatory support or who experience neurologic compromise, more often spend extended time with their heads in fixed positions that promote development of a long, narrow scaphocephalic-shaped head. For a full discussion of plagiocephaly, see Chapter 316, Positional Deformational Plagiocephaly.

## ASSESSMENT AND MANAGEMENT OF PAIN

Early repetitive pain experiences result in permanent changes in pain processing, neuroendocrine function, and development that contribute to abnormal pain thresholds, increased anxiety and stress disorders, and atypical behaviors that include exaggerated startle responses and hypervigilance. Attention should be paid to providing appropriate analgesia to alleviate procedural and postoperative pain. Several measures are available to facilitate assessment of neonatal pain. Among the commonly used measures are the Premature Infant Pain Profile (PIPP), Neonatal Infant Pain Score (NIPS), Neonatal Facial Coding System (NFCS), Neonatal Pain, Agitation and Sedation Scale (N-PASS), Cry, Requires Oxygen, Increased Vital Signs, Expression, Sleeplessness (CRIES), and COMFORT Scale.

## DEVELOPMENTALLY SUPPORTIVE CARE

Preterm and sick infants experience repetitive painful stimuli and prolonged stress, which has both short- and long-term physiological effects on the child. A developmentally supportive neonatal care environment that integrates noise and bright-light reduction, cycling of light exposure to mimic physiological diurnal variations, and grouping of care activities has demonstrated efficacy in supporting the neurodevelopment and self-regulation abilities of the sick and preterm infant. Benefits attributed to developmentally appropriate care include enhanced growth and behavioral outcomes, decreased need for respiratory support, and decreased length of hospitalization. Environmental modifications include

flexed positioning, use of containment to promote state regulation, gel and shape-retaining pillows to provide head support and reduce positional plagiocephaly, adjustable ambient lighting with the use of procedure lights, incubator covers, limiting decibel levels for continuous and transient sounds to less than 50 dB (maximum of 70 dB for transient sounds), and modifying handling and touch in synchrony with the infant's sleep-wake cycles and behavioral responses (cues). For comparison purposes, 45 dB corresponds to noise levels of normal living, talking, or background radio sound; 70 dB is equivalent to average roadway traffic or a vacuum cleaner or quiet hair dryer 1 m away from the ear.

Infants who are most sensitive to stimulation, particularly tactile contacts, are babies who are less mature (<32 weeks PMA), have chronic cardiorespiratory conditions (BPD, cardiac disease), and demonstrate physiological and behavioral disorganization. Parents should be encouraged to touch and hold their infant, providing tactile experiences appropriate to the baby's ability to tolerate stimulation and handling. Beneficial forms of stimulation for preterm and sick infants include nonnutritive sucking, kangaroo (skin-to-skin) care, and infant massage. Nonnutritive sucking provides comfort, facilitates state regulation, and enhances growth and development. Kangaroo care or skin-to-skin contact has demonstrated benefits, including enhanced physiological stability with fewer episodes of apnea and bradycardia, improved sleep-wake cycles, reduced infection, reduced hospital length of stay, and improved lactation and breastfeeding. Infant massage is also beneficial, but requires assessment of the infant's responses to tactile and kinesthetic stimulation (handling and position changes).

## Chapter 113

# DISCHARGE PLANNING FOR THE HIGH-RISK NEWBORN REQUIRING INTENSIVE CARE

Christina Long, DO; Deborah E. Campbell, MD

## INTRODUCTION

One of the most important aspects of caring for a premature or sick infant is the preparation for the infant's discharge from the hospital. The most medically complex infants have often spent weeks or months in a neonatal intensive care unit (NICU) and require a broad array of medical and other services for their postdischarge health care, including primary pediatric care, subspecialty follow-up, home or public health nursing care, early intervention services, extensive care coordination, and family support.

Comprehensive discharge planning is as important as the medical care that the infant received in the NICU; it requires a team approach that includes the neonatologist, pediatric specialists, the infant's primary care physician, hospital nurses, social worker, lactation consultant, therapists, and most important, the infant's family. The family is central to the discharge planning process and vital to its success. Discharge planning is necessary not only for infants who will be discharged home with their families, but also for infants who may be transferred to a transitional or chronic-care facility, such as a children's rehabilitation center.

The transition from the NICU to home can be stressful for the neonate and the family. Preparing the family for a coordinated discharge, with adequate opportunities for parents to assimilate the staff's teaching and to ensure availability of the necessary resources, can help alleviate many of the fears parents have about taking home their premature or medically fragile infant. The infant's primary care physician is an integral member of the team as coordinator of the child's medical home and overseer of the infant's ongoing health and developmental care needs. The hospital-based medical team is responsible for engaging the primary care physician, and ensuring complete disclosure of the infant's medical information and the required follow-up care services. The neonatal team needs to ensure that the pediatrician is also fully informed about the family's material resources, as well as psychosocial and other support needs, so that the parents may properly care for and nurture their infant at home as well as handle their other family responsibilities.

Every neonatal or special care unit has basic criteria that must be met for the infant to be discharged from the acute-care setting. Most units require that an infant demonstrate a sustained pattern of weight gain with effective oral feeding by breast or bottle, be able to maintain a normal body temperature under ambient (thermoneutral) conditions, and maintain a stable cardiorespiratory status with resolution of

apnea, bradycardia, and desaturations. Additional criteria for discharge are evidence of active parental involvement and demonstrated parental ability to adhere to the child's prescribed care. Arranging for timely, appropriate medical follow-up after the infant's hospital discharge is another important aspect of the discharge planning process. Families in rural and other underserved communities may face particular challenges in accessing the needed specialized follow-up care their infants require, placing an additional burden on the family, discharging hospital, and primary care physician.

## FEEDING AND NUTRITION

### Discharge Criteria

Despite advances in nutritional support with attention to early aggressive nutrition, many low-birth-weight or chronically ill infants exhibit slow or inadequate postnatal growth; and among the smallest, least-mature infants, nearly universal growth failure is evident at discharge. The goal of postdischarge nutrition is to provide the necessary nutrients to optimize growth and bone mineralization and promote a pattern of weight gain and head growth that supports appropriate catch-up growth, yet prevents excessive or inappropriate weight-gain patterns that may predispose the infant to adverse health consequences, such as metabolic syndrome later in life. Infants at risk for poor growth include preterm, low-birth-weight, and severely growth-restricted infants, as well as babies born with anatomic abnormalities or neurologic disorders that interfere with effective oral feeding, limit nutrient utilization, or increase metabolic requirements that are not easily met through typical feeding regimens. Infants with complex nutritional needs include those with chronic lung disease, short bowel syndrome, cholestasis, and cardiac disease.

Individual hospitals and health systems have established criteria regarding the specific weight an infant must attain before discharge; many units aim for a weight of 1,800 to 2,000 g. Significant variation exists in the actual discharge weights of NICU infants, given that the infant's comorbidities often determine the timing of discharge, as does the availability of community resources to support the infant with continuing feeding issues and the infant's mode of enteral intake at discharge—oral or via a feeding tube (nasogastric or gastrostomy). Insurance coverage for the infant's post-hospital care may support an earlier discharge for the infant with home nursing care.

For infants with feeding difficulties, the neonatal team, in collaboration with a speech pathologist with feeding expertise, nutritionist, or lactation consultant, must devise a feeding plan with the parents that will support the infant's nutrition and weight gain and that is feasible for the family to implement. A feeding plan should include the type of feeding, amount of feeding, frequency and method of feeding, and any special instructions necessary. For example, some infants may require specialty formulas that require special preparation. The parents and primary care physician should understand the feeding regimen, the nutrition and weight-gain goals, and the parents need to demonstrate their ability to feed their infant appropriately.

During the course of the infant's hospitalization the baby's weight and other growth parameters, length, and head circumference should have been plotted on a standardized infant growth curve, such as the Fenton (Babson-Benda intrauterine and postnatal growth chart) or Olsen intrauterine growth curves that track growth of preterm infants from 22 to 50 weeks' gestation or the 2000 standard growth curves from the Centers for Disease Control and Prevention. The weight-gain goal at discharge and during the transition home is typically 20 to 30 g/day, with an intake of 100 to 120 kcal/kg/day and a volume intake of at least 180 mL/kg/day, unless a particular reason exists that an infant requires fluid restriction. Experts have recently recommended that a more appropriate weight-gain target to promote optimal growth should be 14 to 16 g/kg/day. Many recovering preterm infants without feeding or cardiorespiratory problems who are fed on demand, without volume restriction have daily intakes that range between 170 and 220 mL/kg/day. Preterm infants who are receiving exclusively expressed human milk may exhibit a reduced weight-gain pattern. However, if the infant is consuming more than 170 to 180 mL/kg/day of human milk, then growth patterns comparable to formula-fed preterm infants are seen. Acceptable weight gain for an infant receiving only human milk should also be 20 to 30 g/day. It is important to note that infants discharged home on calorie-dense, enriched feedings may consume smaller feeding volumes because of the earlier satiety induced by the enriched formula's higher fat content. Gastroesophageal reflux is a common problem among preterm and some term infants and may also limit feeding volume and weight gain.

The following aspects of the hospital feeding plan assessment inform a discharge feeding plan:

1. Type of feeding—unfortified or fortified human milk, formula, or a combination
  - Human milk fortifier is often discontinued when the infant reaches a weight of approximately 1,800 g.
  - 24 kcal/oz premature formula (Similac Special Care Formula or Enfamil Premature Formula) may be continued until the infant attains a weight of 1,850 to 2,400 g (4.0–5.5 lb).
  - Some states' Special Supplemental Nutrition Program for Women, Infants, and Children (WIC programs) will provide these formulas postdischarge until the infant reaches 3 to 4 months postnatal age (approximately term-corrected age).
  - 22 cal/oz transitional or postdischarge formula (Enfamil Enfacare or Similac Neosure) is started when the preterm infant achieves a weight of 1,850 to 2,400 g and is continued until optimal growth is achieved, nutritional deficiencies are corrected, or the infant reaches 6 to 9 months corrected age.
  - Sick preterm infants with birth weights between 1,500 and 1,850 g who have required parenteral nutrition and diuretics and are exhibiting suboptimal growth may also benefit from transitional or postdischarge formula if breastfeeding is not the chosen feeding method.

2. Volume of feedings—milk intake (in mL/kg/day) and volume per feeding if bottle fed
  - Goal is an intake of approximately 160 to 180 mL/kg/day.
  - Intakes of less than 160 mL/kg/day are suboptimal.
3. Method of feeding—breast, bottle, lactation aid, cup, tube feeding (oro- or nasogastric tube or gastrostomy tube) or a combination of methods
  - Feeding is suboptimal if the infant cannot consume all feeds orally because of fatigue or poor coordination.
  - Assess the adequacy of the infant's latch and suckling if breastfeeding.
  - Adequacy of growth—average daily weight gain and weekly rate of linear and head growth
  - Growth is deemed adequate when weight (>20 g/day), length (>1 cm/week), and head circumference (>0.5 cm/week) are within normal for corrected age or improving.
  - Growth is inadequate if the weight gain is less than 20 g/day or length gain is less than 0.5 cm/week.
4. Adequacy of nutrition—biochemical monitoring of nutritional status (blood urea nitrogen, phosphorus, and alkaline phosphatase) Oral multivitamin supplementation may be required for the infant who is breastfeeding or ingesting less than 32 oz of formula per day.
  - Until the infant is taking in at least 500 mL/day of formula, vitamin D in a dose of 400 IU/day should be provided.
  - Preterm infants who are exclusively breastfeeding should begin elemental iron supplementation at 2 months of age at a dose of 2 to 4 mg/kg/day.
  - Formula-feeding, preterm infants should receive an iron-fortified formula.

### Transitioning to Breastfeeding

Mothers who have been expressing milk during their infant's hospitalization should be assisted in transitioning to breastfeeding in advance of the infant's discharge. Clinical guidelines are available that offer information for use by both physicians and mothers. High-risk infants who have been receiving fortified feeds should be monitored at least 1 week on unfortified human milk to properly assess the adequacy of growth and nutrient intake. Infants with signs of persistent inadequate growth and nutritional deficiencies (low serum albumin and blood urea nitrogen levels, and elevated serum alkaline phosphatase) and infants who have difficulty completing their feedings will benefit from continued nutritional supplementation after discharge. Determining whether the infant can be fed on demand or needs to continue on a schedule is another important factor to ensure that infants with chronic conditions, feeding difficulties, and feeding fatigue achieve the desired intakes.

Optimally the goal is for the infant to breastfeed rather than for the mother to continue to express milk for administration by bottle. A common parental concern relates to the adequacy of the infant's intake once the mother is no longer able to monitor the baby's oral intake visually. Information and guidance are necessary to foster maternal confidence in her

ability to nourish her infant adequately without benefit of a volume measure. Pre- and postfeeding weights can be measured as a tool to assist mothers in assessing their infant's intake during a feeding. The mother should be counseled to continue expressing or pumping milk at least 3 times daily to maintain her milk supply as she is transitioning the baby for exclusive breastfeeding. Iron and multivitamin supplementation should be started once the infant is receiving unfortified human milk.

### Maintaining the Mother's Milk Supply

Mothers who are expressing milk for their hospitalized infant must often contend with a decreasing or insufficient milk supply during the infant's extended hospital stay. As an adjunct to increasing the frequency of breast pumping, some women use galactagogues, pharmacologic and herbal products, to boost their milk supply. The evidence to support use of these varied medications and herbal substances is limited, based on small studies. Domperidone and metoclopramide are the 2 most widely prescribed medications. Domperidone is not approved for marketing in the United States by the US Food and Drug Administration (FDA), but is available in Canada and other countries. Domperidone is also available from some compounding pharmacies in the US. Metoclopramide (Reglan) use is controversial. It has been shown to be effective in increasing and maintaining milk production in some women in a few small studies. Metoclopramide increases prolactin secretion and is typically prescribed in a dosage of 10-mg tablet taken orally, 3 to 4 times per day for 1 week, followed by a 1-week period during which the medication is tapered. Continuing kangaroo care after discharge is another technique that can improve milk production and encourage faster transition to breastfeeding. Some breastfeeding women prefer to use herbal products or natural foods to increase their milk supply. Herbs commonly used include fenugreek, goat's rue, milk thistle, anise, basil, blessed thistle, fennel seeds, and marshmallow. No standard dosing, preparation, or combinations of these substances exist, and they are not approved by the FDA. Fenugreek, a member of the pea family listed as generally safe by the FDA, may be consumed in capsules or as a tea; side effects are rare, but it can cause hypoglycemia. Goat's rue is recommended in several European countries; used alone, no side effects have been reported. Milk thistle is an herb that, according to the American Herbal Products Association, may be safely consumed during lactation. Mother's milk tea is a blend of plants used to increased milk supply; it is promoted as having no caffeine, and none of the ingredients have pharmacologic actions. Other herbal teas considered safe during lactation include chicory, orange spice, peppermint, raspberry, red bush (rooibos, hibiscus, sorrell) tea, and rose hips. Although the FDA does not approve the use of herbal medicines for lactation purposes, many have been proven safe. However, many herbs, particularly those containing alkaloids, are contraindicated in lactation, including aloe, buckthorn bark, buckthorn berry, cascara sagrada bark, coltsfoot leaf, senna leaf, peppermint oil, caraway oil, kava kava, petasites root, Indian

snakeroot, rhubarb root, senna leaf, Chinese ephedra (ma huang), and uva ursi.

### Special Considerations

If the infant does not gain appropriate weight with unfortified human milk, then 2 to 3 feedings of an enriched premature infant formula (prepared as 22–24 cal/oz; Special Care Formula or Enfamil Premature) or a transitional/postdischarge formula (prepared as 22–24 kcal/oz; Neosure or Enfacare) should be added to the infant's feeding regimen (Table 113-1 provides formula modifications). Several state WIC programs will provide premature infant formulas after hospital discharge if the preterm infant is younger than 90 days postnatal age. The infant should be monitored closely for improved growth. In general, human milk fortifier and preterm formulas typically used during the NICU hospitalization are not usually recommended after discharge because the nutrient content is greater than the infant's needs and because ensuring correct preparation can be difficult. Human milk fortifier is typically discontinued when an infant reaches approximately 36 weeks postmenstrual age and weighs 1,800 to 2,000 g. If suboptimal weight gain or growth continues, then additional supplementation should be provided, with an increase in the caloric density to 24 to 30 kcal/oz.

A similar feeding assessment and formula adjustment should be performed for the formula-feeding preterm infant.

During the hospital course, infants with cardiac, renal, pulmonary, and gastrointestinal disease may require increased calories. This requirement for special nutrition often continues after discharge. Such infants must be discharged home on an appropriate formula that provides adequate nutrition for their metabolic and growth needs. For example, infants with renal disease who are not breastfeeding often require a formula with a low solute load and low phosphorous content (Similac PM 60:40). Infants with a cleft lip and palate require a comprehensive feeding assessment to determine the extent of feeding difficulties and whether special nipples or an obturator are needed to facilitate oral feeding. Babies born with a cleft lip or palate can successfully breastfeed, although the infant may require an obturator if the cleft palate is large.

### Eligibility for the Special Supplemental Nutrition Program for Women, Infants, and Children

An important resource for neonates ready for discharge from the NICU is the WIC program. WIC is a federal-grant program administered by federal and state agencies in each of the 50 states, the District of Columbia, Native-American tribal organizations, and 5 territories that include Northern Mariana, American Samoa, Guam, Puerto Rico, and the Virgin Islands. The WIC program targets the low-income population with infants and children who are at nutritional risk. The program provides supplemental nutritious foods, nutrition education, screening, and referrals to other health, welfare, and social service centers. Applicants must meet all of the eligibility requirements, including categorical, residential, income, and nutritional risks.

Categorical eligibility includes pregnant women (during pregnancy and up to 6 weeks after birth), postpartum women (up to 6 months after the birth of the infant or the end of pregnancy), breastfeeding women (up to the infant's first birthday), infants (up to 1 year of age), and children (up to 5 years of age). Applicants must live in the state in which they apply and have an income at or below an income level or standard set by the state agency to which they apply. Applicants must be seen by a health professional who determines whether the applicant meets nutritional risk criteria. WIC-eligible patients should be referred for enrollment before hospital discharge.

### TEMPERATURE REGULATION

An infant's ability to maintain a normal body temperature is another important criterion used to determine readiness for hospital discharge. This is especially important for low-birth-weight infants and babies exhibiting poor growth caused by a prolonged illness, feeding difficulties, or feeding restrictions that limit fluid and caloric intake. Infants who have underlying neurologic dysfunction may also exhibit difficulty with temperature regulation. The infant who is ready for discharge should be able to maintain thermoneutrality when dressed in infant clothing and covered with a blanket. A normal body temperature in the range of 97.7°F to 99.5°F (36.5°C–37.5°C) with the infant in an open bassinet should be maintained for at least 24 hours. If any evidence of temperature instability exists, the infant should not be discharged. Infants at less than 34 weeks gestation are least likely to be able to maintain body temperature in an open bassinet, although more mature infants may also exhibit difficulty with temperature regulation because they are recovering from serious illness, have limited adipose stores, or have high energy expenditure associated with learning to feed or ongoing cardiorespiratory disease. Infants who are unable to maintain their body temperature under routine ambient environmental conditions should continue to be cared for in a heated isolette. An additional important factor to consider relates to the infant who exhibits a change in the ability to maintain body temperature without a change in the environmental conditions. Temperature instability is a nonspecific, although often present, sign suggestive of infection.

### RESPIRATORY

#### Home Oxygen Therapy and Pulse Oximetry

Some infants discharged from neonatal units will have residual lung disease requiring supplemental oxygen therapy at home. The decision regarding an infant's need for home oxygen therapy is often based on a combination of objective and subjective criteria. The infant's clinical care needs must be balanced with the parents' caregiving responsibilities at home and an assessment of the parents' ability or desire to have their infant home on oxygen. Some parents will prefer having their infant transition to a chronic-care or rehabilitative facility until the infant no longer requires oxygen. Other parents will undertake the challenge of

combining parenting with medical caregiving to bring their baby home sooner. Additional considerations include availability of home health care support, local equipment vendors, and the expertise of the child's primary care physician who will be managing the infant's continuing respiratory care needs at home.

Controversy exists regarding specific guidelines for discharging infants on home oxygen therapy. The concentration of oxygen to be used, its duration, the need for cardiorespiratory monitoring versus pulse oximetry, and strategies for weaning the infant from oxygen are issues of debate. Consultation with pediatric pulmonary specialists who will participate in the infant's postdischarge medical care is an additional important aspect of discharge planning for these infants (see Box 113-1). Individual hospital policies delineate the specific criteria for home oxygen therapy.

Factors to consider when deciding on the necessity for home oxygen therapy include:

- The effect of supplemental oxygen on carbon dioxide retention should be considered before deciding on an oxygen flow.

- Most infants with chronic lung disease are not ready for discharge until their supplemental oxygen requirement is less than 0.5 L/min delivered through a nasal cannula.
- The safety of short-term disconnection from supplemental oxygen should be assessed before discharge.

Assessment of oxygenation during sleep with continuous overnight oximetry or polysomnography is recommended when weaning infants from supplemental oxygen. Discontinuation of oxygen therapy should be based on clinical assessments and documentation of adequate oxygenation in room air.

Preterm infants with residual or chronic lung disease often have brief arterial oxygen saturations less than 90% during feedings, periods of wakefulness, and sleep that are not associated with apnea, bradycardia, or cyanosis. Infants with chronic lung disease are also more likely to have severe oxygen desaturations less than 80%. Improved survival rates and reduced morbidity (chronic lung disease, retinopathy of prematurity) without an increase in cerebral palsy have been

**BOX 113-1 Discharge Criteria for Home Oxygen Therapy**

- Maintains oxygen saturations above 92%–93%
- Can cope with short periods without oxygen if the nasal cannula is removed or dislodged
- No apneic events for a predetermined period
- Immunizations up to date, and palivizumab prophylaxis as appropriate to the time of year for respiratory syncytial virus activity for the region where the child resides
- Parents and caregivers capable of caring for infant on home oxygen therapy
- Satisfactory home environment with a functioning telephone
- Satisfactory home environment with functioning electricity and adequate, functioning electrical outlets
- Home care visit completed (before discharge)
- Parents and caregivers trained on use of oxygen, equipment, and cardiopulmonary resuscitation
- Advice given for smoking cessation
- Advice given regarding avoidance of open-flame use in the presence of oxygen
- Parents or caregivers advised to travel with cylinders and inform their home and vehicle insurance companies
- Appropriate resources for parental help in place and emergency contact telephone numbers given to parents
- Communication with the primary care pediatrician completed (before discharge)

Derived from Balfour-Lynn I, Primhak R, Shaw B. Home oxygen therapy for children: who, how and when? *Thorax*. 2005;60:76–81.

observed among infants born less than 27 weeks' gestation who are maintained with oxygen saturations in the range of 84% to 94%. Desaturations or bradycardias that occur without apnea suggest airway obstruction. Although most neonatal units will not discharge a preterm infant until at least 34 weeks' postmenstrual age, if the decision is made to send such an infant home before 34 weeks' postmenstrual age, then the option of a brief period of home monitoring should be considered, given that episodes of prolonged desaturation for more than 4 seconds occur often during periodic breathing or hypoventilation. Infants who continue to exhibit cardiorespiratory instability with recurrent episodes of desaturation, apnea, or bradycardia requiring intervention should not be discharged from the hospital. The frequency of these episodes and the interventions required may be useful in determining the feasibility of the infant transitioning to a chronic-care facility versus remaining in an acute-care hospital.

Experts recommend that infants with residual lung disease and infants at risk for developing pulmonary hypertension be discharged on home oxygen therapy if they are unable to maintain their oxygen saturation above 93% while breathing ambient (room) air. Infants with chronic lung disease whose oxygen saturation is maintained above 93% on home oxygen with low-flow oxygen have been shown to have a reduced risk of sudden infant death, improved weight gain, lower pulmonary artery pressure and airway resistance, and fewer hypoxemic episodes. The goal for oxygen therapy is to maintain the oxygen saturation equal to or greater than 95% ( $\text{SpO}_2$  range 95%–98%). Oxygen, however, is not benign. Oxygen toxicity can occur in premature infants and contribute to ongoing lung injury, in addition to inhibiting lung healing.

Low-birth-weight infants, in particular very low-birth-weight (VLBW) infants, with severe bronchopulmonary dysplasia (BPD) exhibit significantly lower mean  $\text{SpO}_2$  levels during feeding at 2 to 6 months

corrected age. Infants with severe BPD have higher rates of growth delay (weight <10th percentile) during this period of time as well.

Infants with documented persistent apnea also require home monitoring. Some infants with persistent feeding difficulties may have increased oxygen or air-flow requirements to prevent desaturations during feeding. These infants typically have poor oromotor coordination and may have associated posterior pharyngeal dysfunction causing airway collapse. Provision of low-flow air or low concentrations of oxygen may be beneficial in preventing episodes of desaturations or bradycardia during feeding. A feeding assessment by a qualified speech pathologist with infant feeding expertise will facilitate making this diagnosis and deciding the need for supplemental flow or oxygen during feeding.

After requirements for discharge are met, the required home oxygen equipment (Box 113-2) must be ordered and delivered, and the parents and other caregivers properly trained in the equipment use. Another important decision is the type of home monitoring that is necessary for the infant—a cardiorespiratory monitor or a pulse oximeter. Pulse oximetry is a simple, noninvasive technique for measuring and monitoring arterial oxygenation saturation. However, no evidence has been found that pulse oximetry improves the outcome of babies on home oxygen therapy. Pulse oximetry is notable for frequent false alarms, especially when the infant is active. In addition, oxygen saturation is only 1 measurement of an infant's respiratory status. A sick infant may still maintain normal oxygen saturation while receiving oxygen despite changes in other physiological parameters. Therefore the issue of discharging an infant with pulse oximetry remains controversial, although it is helpful in the periodic assessment of the infant's status with measurement of the infant's oxygenation during activity (bathing, crying), sleep, feeding, and while in a vehicle safety seat or infant seat.

Most third-party insurers have policies guiding their approval process for home oxygen therapy and

### BOX 113-2 Equipment Required for Home Oxygen Therapy

- Oxygen concentrators are preferred with a back-up cylinder and portable cylinder for use during travel.
- Oxygen concentrators require 2 outlets.
- Low-flow meters must provide the appropriate flow range for infants and young children (many require <1 L/min of flow).
- Humidification system is required for some specific flow rates.
- Appropriately sized nasal prongs required, with face mask and extension tubing.
- Lightweight ambulatory equipment is required.
- Families must have functioning electricity and must be provided with documentation for the local electric company to prevent electricity disruption.
- An assessment should be made regarding the need for an emergency generator as a back-up electricity source.

Derived from Balfour-Lynn I, Primhak R, Shaw B. Home oxygen therapy for children: who, how and when? *Thorax*. 2005;60:76–81.

home monitoring for specific groups of high-risk infants. The hospital care managers will coordinate the initial insurance company approvals, but the pediatrician will need to become familiar with the specific insurer's guidelines regarding periods of coverage and authorizations required for continued equipment use at home. The neonatal team, in consultation with the pulmonary specialist, typically determines the concentration of inspired oxygen and equipment required by the infant at discharge and provides the home health care company, equipment vendor, and the family with specific instructions. The equipment vendors typically provide the family with detailed instruction on the equipment setup and use, and provide 24-hour access for technical support and equipment replacement in the event that a problem arises. No consensus exists about the optimal alarm settings required for home oxygen saturation monitoring, although, in general, typical alarm settings are heart rate greater than 200 beats/min and less than 80 beats/min and oxygen saturation less than 80%.

An infant who is discharged on home oxygen therapy requires close medical follow-up. The infant should also have a follow-up visit with a pulmonary specialist, if feasible. In communities where appointments for subspecialty care are not easily accessible for families, the pediatrician will need to have an identified pulmonary specialist with whom to consult on management issues.

### Supplemental Oxygen Requirements During Air Flight

An important, although uncommon, consideration is the potential need for supplemental oxygen during air flight for infants whose families plan air travel after discharge. Commercial air travel has been shown to decrease oxygenation in children. Experts recommend

that children, particularly infants with residual lung disease, undergo a preflight assessment of their response to a hypoxemic challenge to determine their need for in-flight oxygen therapy. If the pulse oximeter saturation decreases to less than 85% during the hypoxic challenge test, then supplemental in-flight oxygen is necessary. For infants with a history of respiratory disease, experts recommend that supplemental oxygen be provided if the pulse oximeter saturation is less than 90%. Most formerly preterm infants who are younger than 12 months corrected age at the time of the proposed air travel and not requiring oxygen supplementation in room air are felt to be at risk for hypoxemia during air flight. However, a recent publication by Bossley et al determined that former preterm infants babies without BPD who are at least 3 months corrected age do not seem to be a particularly at-risk group for air travel, and routine preflight testing is not indicated. It is notable that in this study, feeding babies in a low oxygen environment leads to a further fall in SpO<sub>2</sub>, which is significant but transient.

Infants at highest risk for in-flight hypoxia are younger than 3 months corrected age, irrespective of whether the infant has chronic lung disease. This risk exists even among infants who passed preflight hypoxia testing with SpO<sub>2</sub> levels higher than 85% while breathing an FiO<sub>2</sub> of 0.14 to 0.15. Prudence therefore suggests that if a preterm infant younger than 3 months corrected age must undertake air flight, the infant should be monitored in-flight with supplemental oxygen available if the SpO<sub>2</sub> falls below 85%.

### Home Ventilation

Improving survival rates among medically complex infants with severe cardiorespiratory disease, craniofacial anomalies, and neurologic abnormalities affecting respiratory control have resulted in a group of infants who require long-term ventilatory support and home ventilation. The discharge planning and care coordination of infants needing ventilator assistance at home requires extensive preparation and coordination before the child and family can safely move to a community setting. Before considering home ventilation, the infant must be medically stable, with stable ventilator settings for at least 1 week, and require an FiO<sub>2</sub> less than or equal to 0.4 (40% oxygen), have stable blood gases within the normal range for the infant's diagnosis, and have a secure airway with a mature tracheostomy that is healed (at least 1 week postoperative). The infant should not require intensive care (1-on-1) nursing or invasive monitoring.

The infant's parents must be committed to home ventilation, and adequate home health care personnel must be available, including the parent and at least 1 other person (parent or other family member or a registered or licensed practical nurse). Infants who are being discharged on home ventilation should have professional home nursing for at least 16 hours per day to support the safe transition of the infant from the hospital and ensure the parents' ongoing education and technical skills in managing the respiratory equipment. If other children or individuals with developmental disabilities are in the home, then an intensive assessment should occur as to the feasibility, safety, and appropriateness of the infant's discharge to the home.

The home environment needs to be evaluated by the equipment vendor and the home health care agency to ensure adequate space, electricity, and other utilities, and a safe home environment. The respiratory equipment vendor must ensure 24-hour access and in-home support. The local community emergency medical services providers (fire department and emergency medical system) should be made aware of the infant's home ventilation need. Local utility companies, including telephone and electric companies, need to be made aware of the child's technology dependence to ensure that services are not interrupted. Arrangements for routine and emergency transport of the infant for primary, specialty, and emergency care visits must be clearly detailed. Community resources must also be identified and linkages established to ensure that the infant and family receive appropriate medical, psychosocial, and early intervention services. Parent and other home caregiver education must include tracheostomy care and changing, airway suctioning, medication administration, manual ventilation and resuscitation, and recognition of changes in the infant's status—lethargy or agitation, cyanosis, respiratory distress, temperature instability (hyperthermia or hypothermia), and dehydration.

### Apnea, Bradycardia, and Desaturations

Apnea, bradycardia, and desaturation commonly occur in premature infants. A detailed discussion about the underlying pathophysiological mechanism is provided in Chapter 112, Continuing Care of the Infant After Transfer From Neonatal Intensive Care. The timing of discharge for a preterm infant with a history of apnea, bradycardia, and desaturation is controversial, as is the definition of when the infant can be deemed *medically stable* for discharge. Treatment of apnea, bradycardia, and desaturation depends on its underlying cause. The etiology of these signs further influences the decision regarding the appropriate time for discharge of an infant experiencing apnea, bradycardia, and desaturation. The standard practice is to delay the discharge of premature infants until they have achieved a set duration of days without any apnea, bradycardia, or desaturations.

No standard or universally accepted guidelines exist regarding the duration of this observation period or the effectiveness of delaying discharge. However, among the most immature infants, a period of observation that is too short may predispose a subset of infants to apparent life-threatening events at home. Apnea in the larger preterm infant resolves in most affected infants by 34 to 36 weeks postmenstrual age, with more than 90% of infants being apnea free by 37 weeks postmenstrual age. The duration of apnea is extended, often not resolving until 40 to 43 weeks postmenstrual age, among extremely low-birth-weight infants born at less than 28 weeks' gestation. Premature infants may also exhibit apnea as a developmental process; however, persistent apnea may also occur because of other factors, such as sepsis, temperature instability, sedation, gastroesophageal reflux, and physiological instability in response to positioning and handling. Each infant needs to be evaluated individually when determining the cause of the apnea and the possibility of discharge. Infants requiring treatment

with methylxanthines for apnea of prematurity should have medications discontinued when they reach 32 to 34 weeks postmenstrual age, and be apnea free for 7 to 10 days before discharge if home monitoring is not planned. Infants treated with caffeine require an extended period of observation of 7 days because of caffeine's long half-life; the period of observation after discontinuation of theophylline is somewhat shorter at 4 to 5 days.

Recommendations for the period of symptom-free days before hospital discharge for the infant who does not require home monitoring range from 3 to 8 days. Evidence suggests that continuing hospital care for preterm infants with significant apnea until cessation of apnea for a predetermined duration is a reasonable clinical practice. Infants who have been apnea free for 8 days or more are unlikely to have another apneic episode, unless other associated complications exist. In a survey of neonatal units, the margin of safety for infants with gestational age greater than or equal to 30 weeks between the last documented episode of apnea and hospital discharge was 5 to 7 days. Zupancic et al explored the economic implications of monitoring for resolution of apnea of prematurity for a fixed number of days before discharge home. Results of the economic modeling performed demonstrated a sharp decline in the utility or *value* for the cost of continuing hospital care as the duration of monitoring increased and decreasing cost effectiveness for infants who were born at higher gestational ages. Currently, no studies have established either the efficacy or the cost effectiveness of the various durations of monitoring.

### Predischarge Polysomnography (Event Monitoring)

Predischarge monitoring of infants with a history of apnea of prematurity using 12- to 24-hour pneumocardiogram recordings are a routine aspect of discharge planning in some hospitals. A pneumocardiogram is a diagnostic test that provides a continuous recording of heart rate and respirations that can detect periods of central apnea and periodic breathing. A 4-channel device also employs a nasal thermistor to detect airflow and a pulse oximeter to measure oxygen saturation through the activities occurring during the period of monitoring. The thermistor can help distinguish between central and obstructive apnea. Pneumocardiograms may be used as screening tests to determine which infants are at risk for life-threatening apnea; however, no evidence exists to support predischarge monitoring as predictive of life-threatening apnea or sudden infant death syndrome (SIDS). In addition, although such studies may reveal ongoing episodes of apnea, bradycardia, or desaturation, they reflect the events over a limited time frame and may not identify all infants at continuing risk. The infant being tested may not exhibit signs during the examination. Therefore no current guidelines have been formulated to recommend the routine use of pneumograms in infants with apnea; however, distinguishing the type of apnea that an infant experiences may be useful clinically.

### Home Apnea Monitoring

Apnea monitors were first introduced in the 1960s for managing apnea of prematurity in hospital settings.

Subsequently, home cardiorespiratory monitoring became widely used, with the hypothesis that SIDS might be prevented by monitoring for apnea. No scientific evidence has been found to support the premise that cardiorespiratory monitoring at home reduces the incidence of SIDS or that apnea is a precursor to SIDS. Apnea of prematurity does not predispose an infant to SIDS, although prematurity, itself, is a risk factor for SIDS. The efficacy of home cardiorespiratory monitoring for siblings of infants who died of SIDS has also not been proven. Given the lack of evidence that home cardiorespiratory monitoring has any effect on SIDS, prevention of SIDS is not an acceptable indication for home cardiorespiratory monitoring. Di Fiore et al concluded that infants referred for apnea monitoring studies because of persistent bedside monitor alarms had very infrequent apnea of at least 20 seconds' duration. A high frequency of desaturation and bradycardia was noted in response to short respiratory pauses when compared with infants with no persistent bedside monitor alarms. Some premature infants continue to experience recurrent apneic episodes despite evidence that they are otherwise ready for discharge because they have achieved full oral feeding and demonstrate appropriate temperature regulation. The decision to discharge a premature infant on home apnea monitoring is typically based on the infant experiencing *clinically significant cardiorespiratory events*. These events are defined as apnea greater than 20 seconds' duration, apnea of less than 20 seconds that is associated with bradycardia (heart rate [HR] less than 80 beats/min), a 33% drop in HR below the resting HR or a decline in the oxygen saturation below 85%, bradycardia with an HR less than 80 beats/min, or oxygen desaturation less than 80% for more than 5 seconds. Infants who have experienced apparent life-threatening events associated with apnea, color change, marked change in muscle tone with hypotonia or flaccidity, and choking and gagging should also be considered for home apnea monitoring. Home monitoring until 43 to 45 weeks postmenstrual age may offer an acceptable alternative to continued hospitalization if the parents are in agreement and if close coordination and follow-up care is provided by the pediatrician.

Home monitoring may be also medically necessary and justified for other infants with significant medical conditions. Infants who are technology dependent requiring home ventilation (continuous positive airway pressure or nasal bilevel positive airway pressure), who have a tracheostomy or require home oxygen therapy, or who have neurologic or craniofacial abnormalities that affect respiratory control or function are typically discharged with home monitoring. The AAP offers specific recommendations for home cardiorespiratory monitoring (Box 113-3). Parents and caregivers must learn that home cardiorespiratory monitoring does not guarantee avoidance of sudden death from an underlying cause.

If home monitoring is prescribed, then the parents and other caregivers must be trained in the correct application and operation of the monitor and in infant cardiopulmonary resuscitation (see Tools for Practice). The family should have 24-hour access to an equipment specialist from the home care supply vendor, as

### BOX 113-3 Home Cardiorespiratory Monitoring

- Home cardiorespiratory monitoring should not be prescribed to prevent SIDS.
- Monitoring may be warranted for premature infants who are at high risk of recurrent episodes of apnea, bradycardia, and hypoxemia after hospital discharge.
- Monitoring may be warranted for infants who are technology dependent (tracheostomy, continuous positive airway pressure), have unstable airways, have rare medical conditions affecting the regulation of breathing, or have symptomatic chronic lung disease.
- If monitor is prescribed, then monitor should be equipped with an event recorder.
- Parents should be advised that home monitoring does not prevent sudden, unexpected deaths in infants.
- Pediatricians should continue to promote proven practices that decrease the risk of SIDS—supine sleep position, safe sleeping environments, and elimination of exposure to tobacco smoke.

From American Academy of Pediatrics Committee on Fetus and Newborn. Apnea, sudden infant death syndrome, and home monitoring. *Pediatrics*. 2003;111:914-917.

well as medical support, should questions or problems arise with the equipment or its use. Most insurers have detailed policies that delineate eligibility requirements for the use of apnea monitors. Confirming with individual carriers whether the patient meets the criteria for an apnea monitor according to the insurance company may be necessary.

### Sleep Position

Guidance regarding safe infant sleep and sleep position is discussed in the section on Infant Safety.

### Vehicle Seat Safety

Preterm infants who have achieved readiness for hospital discharge are at an increased risk of respiratory compromise (desaturation, apnea, and bradycardia caused by poor postural tone, hypoventilation, and airway obstruction) when seated in standard vehicle seats. The AAP recommends that all premature infants born at less than 37 weeks gestation at birth be assessed for cardiorespiratory stability in their vehicle seat before discharge. Experts recommend that infants should have a vehicle seat challenge test performed several days before the infant's anticipated discharge date during which the infant is placed in the vehicle seat to be used by the family for 60 to 90 minutes of continuous monitoring. Careful attention must be given to smaller infants who require proper positioning to maintain head, neck, and trunk stability. The AAP has made specific recommendations for the positioning of preterm infants in vehicle safety seats (Box 113-4). In addition, the recommendation is that infants should not be left unsupervised in vehicle seats. Tremendous variation exists among neonatal units in the practice of predischarge vehicle seat testing, and among neonatal units where vehicle

### BOX 113-4 Recommendations for Positioning of Preterm Infants in Vehicle Safety Seats

- Use infant-only, rear-facing safety seats with 3- or 5-point harness systems.
- The vehicle safety seat should be semi-reclined to a 45-degree angle in the rear seat of the vehicle, ideally adjacent to an adult.
- Place the infant's buttocks and back firmly against the back of the vehicle safety seat to reduce slouching.
- The distance from the crotch strap to the seat back should be  $\leq 14$  cm and from the lower harness strap to the seat bottom should be  $\leq 25$  cm.
- Shoulder straps should be in the lowest slots until the infant's shoulders are above the slots.
- Place the retainer clip over the midpoint of the chest rather than on the abdomen or near the neck.
- The vehicle safety seat should not be placed in the front passenger seat of a vehicle with a passenger-side front air bag.
- The infant should not be left unattended in a vehicle safety seat.

Adapted from American Academy of Pediatrics Committee on Injury and Poison Prevention and Committee on Fetus and Newborn. Safe transportation of premature and low birth weight infants at hospital discharge. *Pediatrics*. 2009;123(5):1424–1429.

seat testing is conducted, variation in the indications for testing, duration of the observation period in the vehicle seat, and criteria for *passing* the challenge test exist.

Improper positioning of preterm infants, even infants born at 35 or 36 weeks' gestation, can cause respiratory compromise. Poor postural tone contributes to slouching that can cause neck flexion and airway obstruction. Consideration regarding delaying the discharge home to allow for continued growth and maturation should be given to infants who, despite proper positioning and modifying the seat with blanket rolls or inserts, exhibit desaturations or other signs of cardiorespiratory compromise during the vehicle seat test. Although the recommendation for vehicle seat testing exists, an evidence base is not currently available that confirms the clinical importance of desaturations, bradycardia, or apnea experienced by preterm infants who are classified as *failing* the challenge test or that passing a vehicle seat challenge will improve the outcome in preterm infants.

An alternative transportation device for infants is the vehicle bed. Vehicle beds allow the infant to travel reclining rather than positioned vertically in a vehicle seat. Vehicle beds have been suggested as being more appropriate for transportation of infants at risk for desaturation, apnea, or bradycardia when in a vehicle seat. Vehicle beds can be positioned so the infant is flat or inclined at 30 degrees. Vehicle beds have been recommended for infants with medical conditions requiring prone or supine position, such as premature infants, infants after repair of myelomeningocele, or infants who must lie prone to maintain an open airway (eg, those with Pierre Robin sequence). A recent

investigation by Salhab et al comparing car seat versus car bed for infant transportation found no significant difference in the incidence of apnea, bradycardia, or desaturation in very low-birth-weight infants. Each infant was tested in an infant car seat and a car bed. The reported incidence of 1 or more cardiorespiratory events was 15% and 19%, respectively. Infants with chronic lung disease were more likely to have a vehicle seat event, whereas infants with lower gestational age at birth were at greater risk for a vehicle bed event.

## IMMUNIZATIONS

### Routine Immunizations

Routine immunizations are required for all infants, including preterm and sick infants. Preterm and low-birth-weight infants are at greater risk of increased morbidity from vaccine-preventable diseases than term infants. Therefore gestational age and birth weight should not deter an infant from receiving immunizations on schedule, except with specific criteria for the hepatitis B vaccine. In addition, vaccine doses should not be decreased or altered for preterm or low-birth-weight infants. The anterolateral thigh is the preferred site for administering intramuscular vaccines to preterm and low-birth-weight infants.

If an infant is in the NICU at 2 months of age, then routine vaccines including diphtheria and tetanus toxoids, acellular pertussis, *Haemophilus influenzae* type B conjugate, inactivated polio vaccine, and pneumococcal conjugated vaccine (Prevnar) will have been administered according to the schedule and doses for full-term infants according to the AAP and the Centers for Disease Control and Prevention (CDC). The safety of these vaccines in preterm and low-birth-weight infants is comparable to that in full-term infants, with no increase in adverse reactions noted. Routine vaccinations should also be given at 4 and 6 months of age.

### Hepatitis B Vaccine

Hepatitis B vaccine is recommended for administration at birth or before discharge home from the hospital. Recommendations for administering the hepatitis B vaccine to preterm neonates depend on the maternal hepatitis B status. Infants born to hepatitis B surface antigen-positive mothers will have received monovalent hepatitis B vaccine and hepatitis B immune globulin within 12 hours after birth, regardless of birth weight or gestational age. If the infant's birth weight was less than 2,000 g, then this dose does not count toward the 3-dose hepatitis series. Three additional doses are required beginning at 1 month of age. In addition, these infants should be tested for anti-hepatitis B antibodies and hepatitis B surface antigen at 9 to 15 months of age after the immunization series has been completed.

Medically stable preterm infants and infants weighing less than 2,000 g demonstrate predictable hepatitis B-antibody response and should receive the first dose of monovalent hepatitis B vaccine at 30 days chronologic age, regardless of gestational age or birth weight. If hospital discharge occurs before 30 days, then the infant should be immunized before discharge. These infants should complete the 3-vaccine series, and follow-up

testing is not required. Medically stable infants who receive the vaccine at birth or at 30 days may receive a hepatitis B–containing combination vaccine beginning at 6 to 8 weeks of age, regardless of whether their weight is less or greater than 2,000 g.

### Respiratory Syncytial Virus Prophylaxis

Respiratory syncytial virus (RSV) is an important pathogen that causes lower respiratory tract infections in infants and young children. Premature infants may develop severe, fatal lower respiratory tract infections from RSV. Palivizumab should be given to infants and children younger than 24 months who were infants born at less than 32 weeks' gestation, infants with chronic lung disease, and infants with cardiovascular complications. Infants born from 32 to 35 weeks gestation may be considered for prophylaxis if 2 or more risk factors are present, including child care attendance, school-aged siblings, exposure to environmental air pollutant, congenital abnormalities of the airway, or severe neuromuscular disorders. Infants with chronic lung disease, hemodynamically significant congenital heart disease, or other serious conditions that compromise respiratory or immune function should also be scheduled to receive palivizumab monthly during the RSV season. Some hospital neonatal services provide a referral to the appropriate specialty pharmacy or community-based RSV-prevention program. The pediatrician must be familiar with immunoprophylaxis guidelines, local resources, and specific insurer and state Medicaid eligibility requirements to ensure that infants at risk receive treatment. Seasonal variation can be found in the timing of RSV infection geographically, with additional variation in regional peak infection rates. Palivizumab use should not interfere with the standard immunization schedule.

### Influenza Vaccine

Preterm and other medically fragile infants with chronic medical conditions are at high risk for complications and morbidities associated with the influenza virus infection. Plans for vaccine administration to the infant and family should be included in the discharge summary. If the infant is being discharged from the hospital during influenza season, then the child's parents and household contacts should be strongly encouraged to receive the influenza vaccine, particularly if the high-risk infant is younger than 6 months and is unable to be vaccinated.

### Rotavirus Vaccine

Rotavirus is the most common cause of severe gastroenteritis in infants and young children worldwide. In consideration of the potential risks for and benefits of vaccinating premature infants against rotavirus, the CDC Advisory Council on Immunization Practices (ACIP) has encouraged providers to immunize preterm infants born at less than 37 weeks' gestation between 6 and 12 weeks of age. Limited data suggest that preterm infants are at increased risk for hospitalization from viral gastroenteritis during their first year of life. The safety and efficacy of the rotavirus vaccine seems to be similar for premature and term infants, although relatively few preterm infants have been

evaluated in clinical trials. A theoretical concern exists that lower levels of maternal antibody to rotaviruses in very low-birth-weight premature infants have the potential to increase the risk for adverse vaccine reactions because the vaccine is administered as a live virus. Despite this caution, the ACIP supports vaccination of prematurely born infants if they are at least 6 weeks of age, are being or have been discharged from the hospital, and are clinically stable. The ACIP considers the benefits of vaccination of preterm infants against rotavirus to outweigh the theoretical risks. No safety or efficacy data are available regarding administration of rotavirus vaccine to immunocompromised infants. Rotavirus vaccine should also be deferred for 42 days after any administration of immune globulin.

### HEARING SCREENING

Universal newborn hearing screening has become the standard of care in the United States; currently more than 90% of newborn infants are screened before hospital discharge. The overall rate of permanent hearing loss at birth is 1 to 2 per 1,000 live births. The prevalence of hearing loss increases with a child's advancing age because of progressive losses caused by genetic, hereditary, and acquired conditions, as well as environmental exposures. Among healthy newborn infants the incidence of permanent childhood hearing loss is 0.9 in 1,000, in comparison with a prevalence of 9 to 13 per 1,000 or 5% to 10% of infants requiring neonatal intensive care. The cause of hearing loss in childhood is equally distributed among hereditary or genetic conditions and environmental hazards or acquired conditions.

Infants who are at risk from environmental and acquired causes include those born preterm, babies with persistent pulmonary hypertension (particularly if extracorporeal membrane oxygenation and inhaled nitric oxide are required), those with TORCH infections (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) and bacterial meningitis, and infants with significant hyperbilirubinemia. Among infants who have experienced persistent pulmonary hypertension, 17% to 30% will develop progressive sensorineural hearing loss. As a group, high-risk neonates are 10 times more likely to experience sensorineural hearing loss. Hyperbilirubinemia, prematurity, exposure to ototoxic medications, hypoxia, and infection predispose infants to auditory neuropathy (AN) and auditory dys-synchrony (AD). Infants with AN-AD have abnormal sound transmission to the brain and will have normal otoacoustic emissions (cochlear function) but will have abnormal brainstem-evoked responses (response to sound and the auditory neural pathway). Preterm infants who are born at 23 to 28 weeks' gestation experience the highest rates of AN-AD and sensorineural hearing loss and have a higher prevalence rate for AN-AD compared with more mature infants. In addition, young-for-gestational-age and low-birth-weight preterm infants with AN-AD have increased exposure to potentially ototoxic medications, an increased incidence of bronchopulmonary dysplasia, and extended hospitalizations. Prolonged hospital courses are caused by their multiple medical

complications: intraventricular hemorrhage or periventricular leukomalacia, gastroesophageal reflux, retinopathy of prematurity, cholestasis, osteopenia, and anemia.

Newborns who require an extended period of neonatal intensive care, particularly those with additional risk factors, are at risk for delayed-onset or progressive hearing loss. In addition to a hearing screen before discharge, these newborns should receive audiologic monitoring every 6 months until 3 years of age, as recommended by the Joint Committee on Infant Hearing. The indicators are listed in Box 113-5. (See Chapter 26, Auditory Screening, for more information.) Discharge planning for infants in the NICU should include newborn hearing screening, preferably using a 2-stage screening approach, with the initial screen performed to assess the infant's auditory brainstem response. If the infant does not pass this test, then otoacoustic emission testing should be initiated. Infants may be tested as early as 30 weeks postmenstrual age, although the optimal time for the initial hearing screen is when the infant is at least 34 weeks postmenstrual age. Infants who are at risk must

be screened because infants requiring neonatal intensive care have been found to be more likely to miss predischarge screening for hearing loss. An important point to note is that mild (20–40 dB) and low (conductive)–to-middle frequency (500–2,000 Hz) hearing losses will not be identified by newborn hearing screening. Continued hearing surveillance and periodic hearing testing are necessary for infants at risk for delayed onset and progressive hearing loss. Infants who fail or miss NICU screening must have follow-up testing scheduled. Infants with known hereditary (genetic) or acquired conditions associated with a high risk for late onset or preprogressive hearing loss should be referred for a comprehensive medical and otologic evaluation.

## NEWBORN SCREENING

Newborn blood spot testing for a variety of metabolic, endocrine, and hematologic disorders is routine throughout the United States, the District of Columbia, Puerto Rico, US Virgin Islands, and Guam. Premature and sick neonates will often have serial testing performed during their NICU hospitalization based on established state protocols. In contrast to healthy newborns who have their newborn blood spot test obtained at 2 to 3 days of age, sick and preterm newborns have their initial newborn screening sample obtained during the first hours of life because of the need for blood product administration or early initiation of parenteral nutrition. The amino acid contained in parenteral nutrition solutions can cause elevations in various amino acids levels (eg, phenylalanine, tyrosine), leading to a false-positive test result. Blood transfusions can also result in elevation in the blood spot hemoglobin A level; this elevated level will be detected on the newborn screen in states that test for hemoglobinopathies. Therefore screening tests will need to be repeated 3 to 4 months after a transfusion.

State screening protocols require repeat blood spot screens at 1 to 2 weeks and at 1 month of age for infants requiring prolonged hospitalization. Infants transferred to another facility should have their screening test before transfer, and then coordinated follow-up between the medical care providers is required to ensure test results are known. Sick and extremely preterm infants often exhibit transient abnormalities in thyroid function that require monitoring to ensure that persistent thyroid dysfunction is not missed. Another common abnormality identified on the early newborn screening tests of premature infants are elevations in 17-hydroxyprogesterone (17-OHP) levels, suggestive of congenital adrenal hyperplasia. However, preterm infants often have high blood 17-OHP levels that decline as they mature. Weight-adjusted 17-OHP values may be used to reduce the incidence of false-positive results in premature neonates. Cystic fibrosis (CF) screening is included in the newborn screening panel in many states. The test process involves detection of immunoreactive trypsinogen (IRT) activity and cystic fibrosis transmembrane conductance regulator (CFTR) mutations.

Current mutation analysis encompasses the gene mutations common among white individuals but does not detect the mutations more typically occurring in black patients. IRT levels may be elevated,

### BOX 113-5 Risk Factors or Indicators for Infants With Delayed-Onset or Progressive Hearing Loss

1. Parental or caregiver concern regarding hearing, speech, language, or developmental delay
2. Family history of permanent childhood hearing loss
3. NICU stay more than 5 days, assisted ventilation more than 10 days, prolonged exposure to ototoxic medications (gentamicin and tobramycin) or loop diuretics (furosemide)
4. Postnatal infections associated with sensorineural hearing loss, including bacterial meningitis
5. In utero infections such as cytomegalovirus, herpes, rubella, syphilis, and toxoplasmosis
6. Neonatal indicators (eg, hyperbilirubinemia at a serum level requiring exchange transfusion, conditions requiring extracorporeal membrane oxygenation)
7. Stigmata or other findings associated with a syndrome known to include a sensorineural or conductive hearing loss or eustachian tube dysfunction
8. Syndromes associated with progressive hearing loss such as neurofibromatosis, osteopetrosis, and Usher syndrome
9. Neurodegenerative disorders
10. Head trauma
11. Recurrent or persistent otitis media for at least 3 months
12. Physical findings such as a white forelock associated with a syndrome known to include a sensorineural or permanent conductive hearing loss
13. Chemotherapy

NICU, neonatal intensive care unit.

From Joint Committee on Infant Hearing, et al. Year 2007 position statement: principles and guidelines for early hearing detection and intervention programs. *Pediatrics*. 2007;120(4):898–921.

causing false-positive test results in many conditions, including perinatal distress and prematurity; levels may be low (false-negative test) in infants with meconium ileus. Infants with meconium ileus are at risk for CF and should have a follow-up sweat test, even if the newborn screen is negative. Infants with abnormal IRT levels or identified CFTR mutations require a postdischarge sweat chloride test. Any newborn with an abnormal blood spot screen should have a repeat test before hospital discharge. The need for postdischarge testing will be based on the hospital-based test results. These newborns should be monitored for any signs or symptoms of the diagnosed disorder until the repeat screening results are available. Physical or metabolic signs suggestive of the presence of a screened condition should prompt appropriate diagnostic testing for the suspected disorder immediately.

### RETINOPATHY OF PREMATURETY SCREENING

Conducting a thorough ophthalmologic evaluation and ensuring close follow-up care after hospital discharge are important aspects of eye care for extremely premature infants. Infants whose birth weight was less than 1,500 g or gestational age less than or equal to 30 weeks, and selected infants with a birth weight between 1,500 and 2,000 g or gestational age greater than 30 weeks who experienced an unstable clinical course, including the need for cardiorespiratory support or who are thought to be at high risk, require ophthalmologic evaluation for the presence of retinopathy of prematurity (ROP). If the infant is to be discharged or transferred from the NICU before the first ROP examination at 4 to 6 weeks postnatal age, then an eye examination should be scheduled. If concern exists about the family's ability to comply with the appointment or the availability of ophthalmologic examination at the transfer hospital, then consideration should be given to completing the initial examination performed before the infant is discharged. Communication with the pediatric ophthalmologist and family is

necessary to ensure coordination of follow-up eye care. Table 113-2 and Box 113-6 provide a summary of recommendations for continuing ophthalmologic care.

Some infants may experience adverse effects from the medications used to dilate the infant's eyes. Side effects include sweating, tearing, eye swelling,

#### BOX 113-6 Schedule of Follow-up Examinations for Retinopathy of Prematurity (ROP)<sup>a</sup>

##### 1-WEEK OR LESS FOLLOW-UP

- Immature vascularization in zone I (no ROP)
- Immature retina extends into posterior zone II, near the boundary of zone I
- Stage-1 or -2 ROP in zone I
- Stage-3 ROP in zone II
- Presence or suspected presence of aggressive posterior ROP

##### 1- TO 2-WEEK FOLLOW-UP

- Immature vascularization in posterior zone II
- Stage-2 ROP in zone II
- Unequivocally regressing ROP in zone I

##### 2-WEEK FOLLOW-UP

- Stage-1 ROP in zone II
- Immature vascularization in zone II; no ROP
- Regressing ROP in zone II

##### 2- TO 3-WEEK FOLLOW-UP

- Stage-1 or -2 ROP in zone III
- Regressing ROP in zone III

arrhythmias, apnea and bradycardia, hypertension, and eye irritation. In addition, the examination may be uncomfortable and stressful for the infant. Consequently, medically fragile infants require close monitoring after the examination. Infants at risk for ROP are also at risk for other eye disorders: strabismus, amblyopia, and cataracts. Infants with suspected congenital infection should undergo an ophthalmologic examination before discharge. If this examination is not possible before discharge, then a follow-up appointment should be made as soon as possible after discharge.

## NEUROLOGIC EVALUATION

Premature and sick infants are at risk for brain abnormalities, including intraventricular hemorrhage, periventricular leukomalacia, perinatal stroke, hemorrhagic lesions from birth trauma, or encephalopathy, among other cerebral injuries. Both preterm and term neonates are vulnerable to hemorrhagic and ischemic injury. These abnormalities may lead to poor neurodevelopmental outcome. With advancing techniques in the area of ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI), information can be obtained that may help predict the infant's neurodevelopmental outcome.

Hemorrhagic brain lesions may involve the germinal matrix and the ventricles and extend into the brain parenchyma. Routine cranial ultrasonography is often performed in preterm infants and babies suspected of having intracranial abnormalities. Postdischarge neurosonography for ongoing surveillance of resolving hemorrhages, residual ventriculomegaly, or evolving periventricular leukomalacia or extraaxial fluid collections may be required. The American Academy of Neurology (AAN) recommends that routine cranial sonographic screening be performed between 7 to 14 days of age on all newborns less than 30 weeks postmenstrual age. A repeat scan should be performed between 36 and 40 weeks postmenstrual age to detect the presence of periventricular leukomalacia. Screening at these times can guide clinical care and inform predictions regarding the newborn's potential long-term neurodevelopmental outcome.

The AAN does not currently recommend that conventional MRI of the brain be performed on preterm infants with abnormal screening cranial ultrasounds because evidence as reviewed in 2002 was insufficient to support the utility of MRI in prediction of long-term outcome. However, recent studies suggest a role for MRI at term-postmenstrual age in predicting neurodevelopmental outcome.

Individual hospital policies guide the level of sedation—conscious sedation or general anesthesia—required for completion of the MRI so as to limit motion artifact caused by infant movement. In addition, hospital policies may vary if the infant is an inpatient or an outpatient. If sedation is used, then the infant should be monitored after the procedure for evidence of cardiorespiratory depression, apnea, bradycardia, or desaturations. If an MRI is to be performed before the infant's discharge, then it should be obtained a few days before the anticipated discharge if feasible.

For term newborns who experience birth trauma, neonatal encephalopathy or seizures or have evidence of a perinatal stroke or other brain injury, a noncontrast CT scan and MRI are typically performed early in the neonate's hospital care. Follow-up studies are often performed 2 to 3 weeks after birth to provide information about the evolution of the brain injury and about the infant's prognosis. Discharge planning for these newborns requires follow-up neurologic care and referral to early intervention for periodic developmental surveillance or therapeutic services based on the child's specific needs.

## SPECIALTY FOLLOW-UP CARE

Many infants who are ready for discharge from the NICU have experienced medical conditions requiring consultations with pediatric specialists. For example, infants with suspected (abnormal echocardiograms) or confirmed heart disease, neurologic injury or signs of neurologic dysfunction, renal dysfunction, or chronic lung disease, should have pediatric specialty follow-up appointments. Because of geographic variations, it may not be possible for parents to bring their infant for follow-up appointments with subspecialists. Often, the pediatrician must address these issues while consulting with the specialists. Some tertiary-care centers offer comprehensive neonatal or condition-specific follow-up programs (craniofacial center, spina bifida clinic) in which provide an opportunity for the infant to be assessed by a multidisciplinary team of specialists. Though coordinated, comprehensive care is optimal, insurers and state Medicaid guidelines may not provide reimbursement for multiple visits in a single day or specific components of the child's specialty care. This circumstance can present a challenge to both the family and pediatrician.

## LABORATORY STUDIES

Discharge planning of a patient from the NICU may include obtaining specific laboratory tests to provide a baseline for the infant's biochemical or hematologic status at the time of hospital discharge. Decisions about what studies are necessary should be based on the infant's specific medical issues. For example, an infant with anemia should have a recent complete blood count and reticulocyte count before discharge. If the patient will be discharged on medications that require periodic drug level monitoring, such as phenobarbital, then drug levels should be obtained before discharge to ensure appropriate medication dosing. If the infant is on medications that can cause electrolyte abnormalities, such as diuretics, then a basic metabolic profile should be obtained. The infant with residual renal or liver dysfunction or metabolic bone disease (osteopenia) should have the appropriate studies to establish the infant's biochemical status at the time of discharge. The infant with cholestasis should have a liver function profile drawn. A baby with osteopenia should have calcium, phosphorus, and alkaline phosphorus levels checked before discharge. If patients are receiving medications to treat these disorders, then the dosages may need to be adjusted before discharge. Information about the proposed timing for any follow-up testing, if required,

should be included in the infant's discharge recommendations.

## CIRCUMCISION

Parents of medically stable male infants may request a circumcision before hospital discharge (see Chapter 89, The Circumcision Decision). The procedure may be performed by various medical professionals, including neonatologists, pediatricians, pediatric surgeons, obstetricians, and urologists. Circumcising a very-preterm infant who may weigh less than 2,000 g at the time of discharge may present a challenge because of the infant's small size. The person performing the circumcision should be experienced with the procedure in the preterm infant. Prematurity is not a contraindication for circumcision; however, the infant should be clinically stable before circumcision. No weight criteria or requirement exists for a specific penile size for a premature infant to have a circumcision performed; however, most institutions will delay circumcision until an infant is ready for discharge. An important point to remember is that preterm infants undergoing a circumcision may exhibit cardiorespiratory compromise in response to pain and the stress of the procedure. Monitoring these infants for a brief period after the procedure may be necessary. As with any infant undergoing a circumcision, appropriate pain management should be provided.

## SOCIAL SERVICES AND CASE MANAGEMENT

Most hospitals have mechanisms to identify infants at social and environmental risk. Many neonatal units have established policies that offer the opportunity to or require that all families meet with a social worker. Social workers and case managers play an essential role in the care of any infant admitted to the NICU. They can assess the family constellation and family dynamics, identify risk factors that have the potential to influence the infant's care and family functioning, identify resource needs, and evaluate the adequacy of future home environment. Social workers also serve a vital role as advocates and support for all family members during the infant's NICU stay and can assist in assessing the mother for perinatal depression. They may also serve as liaisons between medical caregivers and community resources, such as child welfare agencies, that service at-risk children and families or community-based home health care programs. Social workers and care managers also assist in coordinating the discharge planning process, especially ordering equipment that the infant might need at home, such as an apnea monitor or oxygen-delivery system. The social worker can facilitate the preparation of paperwork that the parents might need.

## INSURANCE COVERAGE

### Third Party

On admission to the NICU, hospital personnel routinely verify insurance coverage for an infant and will assist the parents in obtaining necessary

coverage, depending on the child's medical needs and the specific terms of the existing insurance policy. In preparation for discharge, some important assessments include the scope of the infant's insurance coverage, and the scope of services covered for continuing outpatient and inpatient hospital care, primary pediatric, and subspecialty care, as well as coverage for durable medical equipment. Individual states have guidelines that determine Medicaid eligibility, physically handicapped children's program eligibility and requirements regarding potential exemptions from enrollment in Medicaid managed-care programs for children with special health care needs. Insurance carrier-driven policies may alter the infant's follow-up care because subspecialty follow-up may need to be with a different medical professional, based on physician insurance plan participation.

### Medicaid

Medicaid is the single largest insurer of children and is an important health resource, especially for children with special health care needs. Medicaid functions on the state and federal level. However, eligibility requirements, as recommended by the AAP, fall under federal legislation.

### Social Security

Many medically complex and extremely low-birth-weight infants are eligible to receive Supplemental Security Income in addition to Medicaid. Neonates born with birth weights less than 1,200 g or who have medical complications such as blindness, deafness, or cerebral palsy may be eligible for Supplemental Security Income. The Social Security Administration eligibility requirements are available at [www.ssa.gov](http://www.ssa.gov).

### Home Health or Public Health Nurse Visit

Infants who are ready to be discharged home from the NICU should have a home nursing visit scheduled, preferably within the first 2 days of discharge. Home nursing visits allow for a medical evaluation of the NICU graduate who is at home and in the care of the infant's parents or caregivers. Home nursing is also a resource that allows parents an opportunity for follow-up immediately after discharge. In addition, some infants may require a predischARGE home visit, which can provide the medical team with information on potential safety problems that the infant may encounter after discharge. For example, if electricity is not working in the home, an infant's health may then be compromised. A predischARGE home visit is important to assess the adequacy of the home environment and parental readiness for the infant's homecoming and can assist parents in their preparation for the infant's discharge. Individual hospital policies guide the specific discharge planning processes and define personnel roles and care-coordination responsibilities.

## PARENT EDUCATION

Ideally, parental involvement in the care of a sick infant should begin at the time of the infant's admission to the NICU. Parental participation is vital during the

NICU hospitalization and can aid the transition to home at the time of discharge. Parent involvement allows the parents the opportunity to gain an understanding of their infant's medical problems and become more comfortable with caring for and nurturing their infant. Ample time should be devoted to parent and other caregiver education.

## INFANT SAFETY

### Cardiopulmonary Resuscitation Training

Infants being discharged home from the NICU may be at continued risk for a health crisis and other apparent life-threatening events that may require cardiopulmonary resuscitation (CPR), such as apneas, bradycardias, and choking. Teaching parents and other caregivers the basic steps in CPR is a necessary part of discharge planning. A variety of tools are available to assist in CPR training, with personal training models available to teach parents and caregivers CPR, including videos or basic course instruction. Teaching materials are available from the American Heart Association. *Infant CPR Anytime* is a self-directed learning program that allows families and caregivers to learn core skills of infant CPR and choking prevention. The kit contains an infant manikin, practice video, sanitizing wipes, and reference guide ([www.aap.org/family/infantcpranytime.htm](http://www.aap.org/family/infantcpranytime.htm)). CPR teaching should be completed before the infant's discharge.

### Sleeping Position

Prone sleeping position is a risk factor that has been identified for SIDS, and importantly, can be modified. Parents of all infants should be educated about the risk factor of prone sleeping and SIDS. Not only the parents, but also all caregivers should be educated. Prone sleeping has been recognized as a major risk factor for SIDS, with odds ratios ranging from 1.7 to 12.9 in various studies.

Discussing sleeping position with parents before discharge is extremely important because many preterm infants are maintained in a prone position during the early stages of their NICU care. Parents and caregivers must be helped to understand that while the infant is hospitalized, the infant is on a cardiorespiratory monitor and under medical supervision. This positioning is often used as an adjunct to improve gastrointestinal reflux and other symptoms such as apnea in some infants and to facilitate development care and flexed positioning. Consequently, parents often believe that because the infant was placed prone in the NICU, this position is optimal for the infant or that the baby *became accustomed to that position* and is uncomfortable when placed supine. Preterm and low-birth-weight infants are at an increased risk for SIDS, and data suggest that the prone sleep position is a major factor in the incidence of SIDS in these patients. Bhat et al demonstrated that, compared with term infants, premature infants ready for discharge sleep with fewer arousals and more central apneas in the prone position. Apnea of prematurity does not increase the risk of SIDS for premature infants. Premature and low-birth-weight infants should be placed supine to sleep.

Parents should be encouraged to place their newborn infants in a crib or bassinette to sleep rather than leaving the baby in an infant seat or car bed. A recent controlled trial demonstrated that hypoxic events occurred more often among healthy full term infants allowed to remain in an infant/car seat or car bed for more than 90 minutes in comparison with placement in a crib. This raises additional concern for preterm infants and babies who have been sick or have residual cardiorespiratory or neuromuscular disease.

### Exposure to Secondhand Smoke

Many preterm and chronically ill infants have evidence of residual lung disease at the time of hospital discharge. Infants exposed to secondhand smoke from tobacco are at risk for medical conditions such as allergies, asthma, ear infections, pneumonia, permanent lung changes, SIDS, and learning disabilities. However, premature infants are especially at risk. Parents and family members should be counseled about smoking cessation long before an infant is ready for discharge. Educating the parents and providing them with resources for smoking cessation can aid them and sometimes motivate them to quit smoking. Different pharmacotherapies, nicotine replacement therapies, and behavioral-modification programs exist to help with smoking cessation. In addition, the Smoke-Free Home Project is a comprehensive, national effort to teach pediatricians methods to reduce children's secondhand smoke exposure through parental smoke cessation and harm reduction.

Mothers who are breastfeeding should be encouraged not to smoke and should be provided with information about smoking cessation and a referral to a smoking-cessation program. If they cannot stop smoking, then these mothers should be encouraged to reduce the number of cigarettes smoked and to switch to a low-nicotine cigarette. Mothers who continue to smoke should be instructed to breastfeed before smoking a cigarette and to delay nursing or to express milk after smoking. Despite their tobacco use, mothers who smoke should be encouraged to continue breastfeeding because the benefits to the infant outweigh potential risks. Breastfeeding mothers who desire to quit smoking may safely use the nicotine gum or nicotine transdermal patches. Safety in lactation has not been determined with nicotine gum; however, the gum exposes the infant only to nicotine and its metabolites and not the effects of smoking. Nicotine patches are designed to deliver a precise amount of nicotine transdermally over time. The infant is exposed to the effects of nicotine in the mother's milk. However, fewer effects occur than with smoking, and compared with other forms of nicotine therapies, the patch is more predictable.

### Preparation for Caregiving at Home: Rooming In

One technique to support parents also affords the family the opportunity to gain confidence in caring for their infant at home is rooming in with the infant for a defined period, during which time the parents assume all caregiving responsibilities. Support from the NICU

staff is immediately available for answering questions or solving problems.

## PRESCRIPTIONS AND MEDICATION ADMINISTRATION

Many infants will be discharged on multiple medications. Parents should have the medications filled before the infant's discharge, and they should be able to demonstrate their ability to administer the medications at the appropriate time and in the appropriate dose. Parents should be instructed to avoid adjusting or discontinuing medications on their own. Discussion should include assessment of the parents' understanding of the reason for each medication and what adverse effects, if any, to anticipate. Many NICUs have developed medication logs and care diaries as tools to help parents and caregivers keep track of their infant's treatments and other care. This tool can be helpful for infants on multiple medications, those with technology dependence, or those in families with multiple births.

## CHILD FIND AND EARLY INTERVENTION

Preterm infants and any full-term neonate who require neonatal intensive care may be at risk for developmental delays and disabilities. The Individuals with Disabilities Education Act requires all states to have a "comprehensive Child Find system" to ensure that all children in need of early intervention or special education services are located, identified, and referred. State-specific eligibility requirements vary, although all programs are guided by federal regulations. Some states have elected to serve children who are at risk of developmental disability, even if the actual diagnosis has not been made.

Examples of eligibility criteria for referral to the Child Find system portion of the early intervention program include the following:

- Infants born at less than 32 weeks' gestation or with birth weights less than 1,500 g
- Infants who spend 10 days or more in the NICU
- Infants with prenatal exposure to drugs of abuse
- Infants exposed prenatally to therapeutic drugs with known developmental implications (antineoplastic, anticonvulsant, and psychotropic drugs)
- Any infant at risk for a developmental delay

Infants who are also at risk for developmental delay may include infants with suspected hearing loss and infants with experienced meningitis, a birth injury, or head trauma. Many infants will automatically meet eligibility requirements. These requirements vary from state to state, however, and include infants with chromosomal abnormalities, genetic disorders, inborn errors of metabolism, disorders of the nervous system (neural tube defects), congenital infections, low birth weight (criteria vary by state), extreme prematurity (criteria vary by state), severe sensory impairment, HIV and severe infectious disease, toxic exposure, cerebral palsy, grade-III and grade-IV intraventricular hemorrhage, hydrocephalus, neuromuscular disorders, disorders of sense organs, brain injury, and technology dependency (tracheostomy).

## DISCHARGE SUMMARY AND FOLLOW-UP CARE

Follow-up care of the discharged NICU graduate is essential to the medical care of the neonate. The primary care physician should receive a detailed summary of the infant's hospital course and continuing care needs. Optimally, the NICU staff should communicate personally with the pediatrician to discuss and evaluate the salient issues for the child and family. Consideration should be given to allocating additional time for the initial primary care visit because the physician not only has to become familiar with the child's prior and current medical issues, but also has to ascertain from the parents how the first days at home have gone and what their particular concerns may be. Follow-up specialty appointments should also be scheduled before the infant's discharge. The timing of initial pediatric primary care appointment depends on individual patient medical problems. For high-risk infants the follow-up appointment should occur within a few days of NICU discharge. Parents should be given a copy of the infant's medical summary and a schedule of follow-up appointments at the time of discharge (Figure 113-1 and Figure 113-2).

### Discharge Summary

#### History of Present Illness:

Include pertinent maternal, pregnancy, and birth history; Apgar score; and admission assessment (infant's gestational age, weight, length, head circumference, and critical vital signs and laboratory results).

#### Neonatal Intensive Care Unit (NICU) Problems:

Include all of the problems the infant was diagnosed with during the admission, and indicate which problems are currently diagnoses.

#### NICU Course by Systems or Medical Problems:

Make sure to include a section for routine health care maintenance issues, such as immunizations, neurosonographic examinations, and newborn screening tests (newborn screen, retinopathy of prematurity, and hearing).

### Assessment

#### Discharge Plan and Follow-up Care:

Include appointment with primary care pediatrician, subspecialty appointments, pending laboratory or diagnostics tests, Child Find referral, and plan for discharge nutrition, medications, monitoring, and any ongoing treatments.

**Figure 113-1** Sample discharge summary format.

### Neonatal Intensive Care Unit Discharge Planning Checklist

Name: \_\_\_\_\_ Medical Record Number: \_\_\_\_\_

Category	Item	Check	Comment
General admission	Primary care physician	<input type="checkbox"/>	
	Maternal laboratory tests and blood type	<input type="checkbox"/>	
	Integrated medical delivery system (IMDS)	<input type="checkbox"/>	
	Medicaid or insurance for infant	<input type="checkbox"/>	
	Complete physical examination	<input type="checkbox"/>	
Home, placement	Discharge to rehabilitation center; send summary	<input type="checkbox"/>	
	Acute coronary syndrome (ACS) clearance, if necessary	<input type="checkbox"/>	
	Home care referral	<input type="checkbox"/>	
	Home nursing (if necessary)	<input type="checkbox"/>	
	Equipment needed for discharge (apnea monitor, pulse oximeter, oxygen)	<input type="checkbox"/>	
Tests, procedures	Feeding assessment; speech referral, if necessary	<input type="checkbox"/>	
	Child-Find or early interventions	<input type="checkbox"/>	
	Vaccinations	<input type="checkbox"/>	
	Synagis and referrals for prophylaxis	<input type="checkbox"/>	
	Circumcision	<input type="checkbox"/>	
	Head ultrasound	<input type="checkbox"/>	
	Retinopathy of prematurity	<input type="checkbox"/>	
	Hearing test: otoacoustic emissions (OAE) testing for all, and possible auditory brain-stem response (ABR), if criteria is met	<input type="checkbox"/>	
	Hip ultrasound: if abnormal examination and if female and breach	<input type="checkbox"/>	
	Vehicle seat challenge	<input type="checkbox"/>	
Parent education	General teaching for baby care (ie, bathing, feeding)	<input type="checkbox"/>	
	Medication administration	<input type="checkbox"/>	
	Cardiopulmonary resuscitation	<input type="checkbox"/>	
	Smoking-cessation plan, if necessary	<input type="checkbox"/>	
	Feeding plans: how to mix formula, instructions for feeding	<input type="checkbox"/>	
Final discharge disposition	Rooming in, if necessary	<input type="checkbox"/>	
	Medical clearance	<input type="checkbox"/>	
	Social work and ACS clearance	<input type="checkbox"/>	
	Prescription available to parents before discharge	<input type="checkbox"/>	
	Women, infants, children (WIC) program form and prescription for special formula	<input type="checkbox"/>	
	Discharge physical (including weight, length, head circumference, hips, hernias, red reflex)	<input type="checkbox"/>	
	Parent notification	<input type="checkbox"/>	
	Primary care provider appointment	<input type="checkbox"/>	
	Transfer of responsibility to provincial medical director (PMD)	<input type="checkbox"/>	
	All other appointments	<input type="checkbox"/>

## Chapter 114

# FOLLOW-UP CARE OF THE GRADUATE FROM NEONATAL INTENSIVE CARE

Judy C. Bernbaum, MD

The scope of pediatric primary care for children who require neonatal intensive care will vary depending on the neonate's underlying medical problems and any sequelae that occur. Most infants who require specialized newborn care will need only routine pediatric primary care, with particular attention paid to periodic developmental surveillance of infants with risk factors for developmental delays and susceptibility to certain illnesses. However, among the most immature and sickest neonates, a comprehensive and coordinated approach to care is necessary that integrates

routine health care, medical and surgical subspecialty care, psychosocial and emotional support needs of the family, and periodic developmental screening—the latter to identify early intervention needs and appropriate resources.

Establishing a medical home for the neonatal intensive care unit (NICU) graduate encompasses the same principles that apply to creating a medical home for any child with special health care needs. Parents have become acclimated to a high-technology, fast-paced hospital environment and have come to rely on a particular set of health caregivers. When their infant is discharged from the hospital, parents must transition to a new physician for their child and a health care system that is complex and, at times, fragmented. Some parents will have felt supported during their infant's hospital experience and think they were true partners in their child's care. Other families will have felt disenfranchised, believing that they were not actively included in decision making about their child's care, or will be unhappy with their child's outcome, continuing health and developmental care needs, or uncertain future. Irrespective of their NICU experience, all parents have concerns about how their child will fare at home, their role as parents, and what the future will bring. Parents of technology-dependent infants must adapt to the challenges of negotiating a vast array of home health services, medical suppliers, and early intervention services that add further stressors on family time and functioning, parenting, and economic resources.

### IDENTIFYING INFANTS REQUIRING CLOSE FOLLOW-UP

There are well-defined risk groups of term and preterm infants who will require specialized follow-up care. Infants in these risk groups may be classified based on biologic risk, the need for specific interventions because of significant fetal or neonatal issues, or social-environmental factors that predispose the infant to adverse outcomes. The National Institute for Child Health and Human Development (NICHD), National Institute for Neurological Disorders and Stroke, and Centers for Disease Control and Prevention (CDC) have identified a subset of infants who are at higher risk for adverse developmental outcomes and who require close neurodevelopmental surveillance and follow-up. This group of babies includes extremely low-birth-weight infants ( $\leq 1,000$  g or  $\leq 28$  weeks' gestation) and infants whose neonatal course has been complicated by neurologic abnormalities such as seizures, intracranial hemorrhage/periventricular leukomalacia, or congenital malformations involving the central nervous system. Infants who experienced profound hypoglycemia, hyperbilirubinemia requiring exchange transfusion, or in utero substance exposure are additional important risk groups who require surveillance and periodic screening through 30 to 36 months of age. In addition, the American Academy of Pediatrics (AAP) recommends that infants who have required neonatal intensive care for longer than 5 days receive periodic neurodevelopmental screening within the primary care setting.

Although many tertiary care neonatal centers offer neonatal follow-up care for high-risk NICU graduates, funding for such programs is limited, and many families live far from existing programs. The AAP and the NICHD have published recommendations regarding the role of the primary care physician (PCP) in the follow-up care of high-risk infants, and the components of health and developmental surveillance that should be provided for high-risk, premature infants.

### PREPARING FOR DISCHARGE

In preparation for hospital discharge, some parents have the opportunity to meet or speak with the physician who will care for their child after the infant's hospital discharge. The PCP may have the opportunity to visit the child in the NICU or may, in some community settings, have assumed responsibility for the infant's care when the baby was transferred to a special care or level II NICU for continuing or convalescent care. In other communities, limited and fragmented care present a challenge for both the hospital team planning for the infant's discharge and the family members who must coordinate and schedule appointments and figure out transportation arrangements, juggling their other responsibilities to comply with their baby's health care requirements.

Comprehensive care programs, either community based or hospital based, have been shown to be effective in reducing life-threatening illness in high-risk infants. However, adherence to recommended follow-up medical care is more likely to be a challenge for families of the sickest infants, particularly when multiple medical appointments are necessary. McPherson and colleagues found that children who required 3 or more medical appointments after their discharge from a pediatric intensive care unit were more likely to miss appointments. Of note was the finding that, after hospital discharge, the children were more likely to complete a primary care visit than follow up with a specialist. Infants who have been transferred from tertiary care units to level I or II nurseries for continuing care are more likely to be readmitted to the hospital and fail to adhere to recommended follow-up care. In addition to a detailed written summary of the infant's hospital course that includes recommendations for the early follow-up subspecialty care needs of the infant, direct communication with the NICU staff can facilitate transfer of care and ensure that the PCP has a complete understanding of the infant's history and discharge plan. Identifying barriers that will interfere with the family's ability to comply with the child's recommended care is also important. This information will help assist the health professional in planning the visit length, given that allotting more than 1 new patient time slot may be necessary to properly assess the infant, address parental concerns about the transition home, adjust medications, plan follow-up appointments, and plan for and review equipment needs if the infant is technology dependent.

An important concern for parents bringing the medically fragile infant into a physician's office is the risk to the baby's health because of a possible exposure to individuals who are sick. Minimizing the time spent in the reception and waiting areas and having

the office staff attuned to the concerns of parents of children with special health care needs can increase parental confidence and satisfaction with the primary care experience. Families also need to know the practice's policies for contacting their child's physician during off hours and for emergencies, as well as which hospital emergency room or urgent care facility to use. Transportation requirements need to be discussed and arrangements made for ambulance or other transportation services as necessary to ensure that the child is able to keep appointments.

The degree of care coordination required of the PCP will vary by community, proximity to specialty care, and availability of high-risk follow-up programs for at-risk infants. Some infants will be enrolled in comprehensive follow-up programs that provide some elements of primary care, whereas other babies may be scheduled for periodic neurodevelopmental surveillance or may need to rely on their pediatric caregiver for these aspects of their care.

## MANAGEMENT ISSUES DURING PEDIATRIC CARE

The specific health care needs of an individual infant or child will be based on the complications or sequelae from their original illness or health condition. The child's and the family's needs will change over time as the child transitions through different health and developmental stages; thus, periodically eliciting the family's assessment of their need for information, resources, and support is important. Parents may be at a different transition point than the professionals involved in the child's care and may express needs that are different from what the physician perceives as necessary or important. Initially, the focus tends to be on ongoing medical concerns as well as infant and early childhood development. During middle childhood through adolescence and young adulthood, parental concerns are focused primarily on the child's academic achievement and school performance, behavior, and social skills. For some families, the child's health issues will continue to be problematic. These issues are discussed in detail in Chapter 115, Health and Developmental Outcomes of Very Preterm and Very Low-Birth-Weight Infants, and Chapter 116, Health and Developmental Outcomes of Selected Medically Complex Neonates.

Components of care for high-risk infants from infancy through adolescence are summarized in Table 114-1. The timing for specialized or more in-depth assessments has been recommended as follows: 3 to 4 and 6 to 8 months corrected age (age adjusted for the degree of prematurity [chronologic age minus the number of weeks born preterm]; corrected age is typically used through 24 months), 12 to 14 months corrected age, 18 to 24 months corrected age, 3 to 5 years chronologic age, and at-school age (8 to 10 years). Components of assessment during these visits should include growth, blood pressure and nutrition, neurologic assessment, gross and fine-motor development, language and communication, socioemotional behavior, health status, and health-related quality of life. Cognitive assessments, either comprehensive or limited

using screening or abbreviated intelligence tests, should be performed when the child is 12 and 24 months corrected age, 3 to 4 years of age, and at 6 and 8 years of age. In addition, a screen for autism spectrum disorders should be performed at 18 and 24 months corrected age. Results of standardized screening or comprehensive developmental testing provide important information that will guide referral for diagnostic or intervention services as needed.

## Transition Home Through the First Year of Life

During the initial transitional period from the hospital through the first 3 months at home, parents' primary concerns are typically focused on feeding, weight gain, elimination, sleep, and adaptation to the home environment (crying, state regulation, and social interaction). In addition, parents are worried about the child's risk for infection and other illnesses, having sufficient medical supplies if the infant is technology dependent, and managing multiple medical appointments and early intervention assessments. Common medical problems experienced by the highest-risk infants are listed in Box 114-1. Parents often report an increasing sense of isolation as family and friends return to their own routines and the parents no longer have day-to-day contact with, and support from, the NICU staff. Communication and partnership building with the child's PCP and subspecialists, as well as communication issues *between* parents and with their family and friends, can also present an important challenge. Often, the assistance provided by home health professionals is an added benefit for many families, especially those who have children with complex medical needs.

Establishing routines can be challenging for families because many preterm infants exhibit sleep problems during the early weeks at home. These problems can be related to immature sleep-awake cycles (day-night cycles), disruptions in sleep patterns caused by the need to administer medications, and heightened parental vigilance because of the infant's perceived vulnerability. The last of these issues can lead to the parent overresponding to the infant's nighttime behaviors, resulting in further sleep disruption. Residual neurologic immaturity and emerging muscle tone abnormalities can contribute to difficulty in caring for and calming the infant. Providing the family with strategies to help calm the infant and to support the infant's state regulation will ease the family's adaptation. Swaddling the infant, keeping the infant's arms and legs close to the body, avoiding sudden movements, and gradually introducing stimuli will support the infant's ability to adapt. Demonstrating the infant's abilities during a routine primary care visit can also provide the parents with valuable insights into their infant's capabilities and developmental needs. Remember, especially when discussing normal developmental milestones, to use their child's corrected age.

The first follow-up pediatric visit after NICU discharge should occur within 1 week of the initial hospital discharge. During the first years of life, infants who required neonatal intensive care have higher, though varying, rates of rehospitalization. Among the most

**BOX 114-1 Continuing Health Problems**

- Anemia
- Apnea of prematurity
- Bone mineralization
  - Osteopenia
  - Rickets
  - Fractures
- Cholestasis
- Feeding difficulties, gastroesophageal reflux disease, oromotor issues
- Gallstones
- Growth
  - Incomplete catch-up growth
  - Slow weight gain
  - Poor or excessive head growth
- Hearing problems: progressive or late-onset hearing loss
- Hypertension
- Hypothyroidism
- Malabsorption, short bowel syndrome, enterostomy losses, constipation, dumping syndrome
- Nephrolithiasis
- Neurologic
  - Seizures
  - Hypertonia or hypotonia
  - Intraventricular hemorrhage
  - Periventricular leukomalacia
  - Developmental delay
- Ophthalmologic issues
  - Vision loss and impairment
  - Strabismus, myopia
  - Field defects, eye motility disorders
- Oral health
  - Enamel hypoplasia
  - Delayed tooth eruption
  - High arched palate
- Pain perception: hyposensitivity and hypersensitivity to painful stimuli
- Postanesthesia complications: apnea
- Respiratory
  - Chronic lung disease
  - Airway complications (subglottic stenosis, laryngo-tracheomalacia)
  - Respiratory infections
  - Increased susceptibility to respiratory syncytial virus
  - Cor pulmonale
  - Sudden death
  - Hypoxia
- Scars, hernias
- Seizures
- Sleep problems
- Sudden infant death syndrome
- Use of chronic technologies
  - Supplemental oxygen
  - Home ventilation
  - Nasogastric tube
  - Gastrostomy tube
  - Tracheostomy
  - Parenteral nutrition
  - Cardiorespiratory monitoring
  - Pulse oximetry

immature infants, 45% of very preterm infants are hospitalized 1 or more times, with nearly 50% of them having 2 or more hospitalizations in this period. The most common causes for hospitalization include respiratory illness, apparent life-threatening events, surgery (hernia repair, laser therapy for progressive retinopathy, enterostomy closure, ventriculoperitoneal shunt revision, placement of feeding tubes), and failure to gain weight.

From 3 months corrected age through 1 year of age, parent concerns continue to focus on the infant's feeding, weight gain, and catch-up growth, as well as the infant's general health. As infants mature, they exhibit improvements in state regulation and ability to handle stimulation and social interaction. Among very preterm or chronically ill young infants, these problems may be persistent. Transient muscle tone abnormalities are common during infancy among preterm infants and include high, low, or mixed tone. This may result in postural or movement difficulties that contribute to feeding or sleep problems, positional plagiocephaly, and quality of, delays in, and acquisition of age-appropriate milestones.

Emerging milestones, particularly motor skills, may be a concern as delays in development become more apparent to the parents, their families, or members of the community. Parents of infants who have experienced a neurologic injury (intraventricular hemorrhage, periventricular leukomalacia or hydrocephalus, neonatal encephalopathy, seizures, or microcephaly) will have ongoing concerns about the risk for cerebral palsy and other neurologic sequelae. The need for early intervention often needs to be addressed. Some families will experience continued erosion of their informal social network, further increasing their sense of isolation. Even parents who have strong family supports and well-established informal support networks will experience isolation. Parents often struggle with the inability of their family and friends to understand and empathize with the challenges and concerns the child and family are experiencing or the family's concerns and fears. When appropriate, encouraging families to participate in parent support groups, sponsored by either hospital or community programs, can be a valuable resource in providing support and guidance to families. Interacting with families who have gone

through similar experiences with their child allows them to share their experiences, verbalize frustrations, learn techniques for coping, and realize that their journey with their child is not unique.

### Toddler and Early Childhood Years

Parental concerns from age 1 to 3 typically focus on motor milestones, communication and language skills, and sensory issues. Generally, infants with motor problems continue to improve and, hopefully, make steady progress. Those with persistent abnormalities in muscle tone may be diagnosed with some form of cerebral palsy. Catch-up growth continues during this time. Infants not previously eligible for early intervention services may require referral for evaluation of speech-language or communication problems or persistent delays in other developmental domains that now meet specific state eligibility requirements. During the preschool years, social immaturity, attention difficulties, and hyperactivity occur in 10% to 20% of preterm and other high-risk children. Emerging learning difficulties will be evident in many children, some also with sensory problems. Social immaturity will be a continuing concern for others. Parents should be advised to observe for learning difficulties and seek early remedial assistance from preschool, nursery, or specialized child-care programs. Children should be screened for autism during this period of time, and a formal evaluation should be performed on those who fail the screening process, with appropriate interventions and referrals made for those diagnosed as being on the autism spectrum.

### Growth and Nutrition Management

Growth patterns of an infant who is born low birth weight, who is preterm, or who is ill at birth provide valuable information about the infant's health. Chronic illness, feeding difficulties, malabsorption, gastroesophageal reflux, increased metabolic and nutritional requirements with inadequate nutritional intake or excessive loss, and social-emotional problems can contribute to aberrant growth. Feeding difficulties may be related to poor oromotor skills, respiratory symptoms, fatigue, or reflux esophagitis. Abnormalities of growth associated with intrauterine growth restriction, genetic or chromosomal disorders, congenital infection, or other syndromes can be responsible for reduced growth potential that prevents expected catch-up growth. Growth measurements should be plotted on standard growth charts, correcting for the degree of prematurity until the child is 24 to 30 months corrected age (see section on catch-up growth). For preterm infants born weighing less than 1,500 g, the CDC National Center for Health Statistics recommends that health care providers

- Use the World Health Organization growth charts to monitor growth of infants and children ages 0 to 2 years in the United States, with the measurements plotted using the *corrected* rather than *chronologic* age
- Use CDC growth charts to monitor growth for children 2 years and older in the United States without the need for correction after 30 months of age

Caloric requirements for adequate growth vary, and feeding recommendations should be adjusted

depending on the trends seen when plotting weight on these charts. An excellent resource for guiding the physician through the nutritional needs of the growing preterm and high-risk infant can be found in the AAP *Pediatric Nutrition* handbook, 7th edition.

### Postdischarge Formula or Human Milk Feeding

Healthy preterm infants require 110 to 130 kcal/kg/day, whereas infants with chronic illness may need up to 150 kcal/kg/day to sustain adequate weight gain and growth. At the time of hospital discharge, most infants are gaining about 10 to 15 g/kg/day, comparable to intrauterine growth rates. However, infants who have been born very preterm or who experience serious illness often have residual caloric and nutritional deficits at the time of discharge; most of these infants leave the hospital with a weight below the expected mean for their gestational and postnatal age. Preterm infants also experience greater morbidity during their first year of life, including more hospitalizations and intercurrent illnesses, that can further affect their feeding and growth.

Tremendous variation often exists in infants' human milk or formula intake. Some infants will be feeding well, ingesting more than 200 mL/kg/day, whereas others are barely achieving intakes of 130 mL/kg/day. The caloric density of a feeding has been shown to influence an infant's intake because infants on lower-calorie (less calorie-dense) feedings will feed up to 20% more than an infant being fed a higher-calorie formula. Preterm infants continue to need higher than normal protein intake to replace deficits that accumulate after birth. Optimal postnatal nutrient intakes for preterm infants have not been fully determined. As a consequence, recommendations regarding target intakes for calcium and phosphorus vary. Recommended mineral intakes range from 100 to 160 mg/kg/day to 150 to 175 mg/kg/day of calcium and from 60 to 90 mg/kg/day to 90 to 105 mg/kg/day of phosphorus. At the time of discharge from the hospital, very low-birth-weight infants will often be provided higher intakes of minerals through the use of transitional formulas than are provided by human milk or formulas intended for term infants. When infants reach a body weight of more than 1,500 g and tolerate full enteral feeds, vitamin D intake should generally be approximately 400 IU/day. Infants with radiologic or biochemical evidence of rickets should have efforts made to maximize calcium and phosphorus intake by using available commercial products and, if needed, direct supplementation with these minerals. The heterogeneity in nutritional status among preterm infants and the differences in growth rates related to gestation, illness severity, and gender at the time of discharge present a challenge to determining an optimal feeding regimen. Special nutrient-enriched formulas are available for postdischarge use in North America and Europe that contain additional protein, minerals, and vitamins and provide 22 cal/oz (73 kcal/dL) and 1.8 g protein/dL. However, study results on the effectiveness of these nutrient-enriched formulas in optimizing growth and development have been mixed. When an infant is volume limited (inadequate intake; fluid restricted), formulas can be concentrated to provide

higher caloric density or supplements can be added to formula to increase caloric intake without substantially increasing volume of intake (see Box 114-2). If an infant is not meeting his or her expected weight gain, because of either feeding difficulties or inability to provide adequate caloric intake, referral to a specialist may be a consideration. Speech or occupational therapists often can address feeding difficulties, whereas a dietitian or nutritionist can help with adjusting the diet by making suggestions on the best way to provide adequate nutrition to result in more appropriate growth.

In a small randomized study of preterm infants less than 35 weeks' gestation who were fed either a nutrient-enriched infant formula or a term formula after hospital discharge, Lucas and colleagues found that the infants fed the enriched formula grew better and had better bone mineralization at 6 to 9 months corrected age. Similarly, Cooke and colleagues demonstrated increased protein intake and greater weight, length, head circumference, and lean and fat mass in preterm infants fed nutrient-enriched formula until 6 months corrected age. Comparison infants who received the nutrient-enriched formula only until they reached term gestation or who were fed a term formula exclusively did not demonstrate these results. Between term corrected age and 6 months corrected, both boys and girls exhibited greater growth when fed a nutrient-enriched formula. Carver and colleagues further refined the understanding of the benefits of feeding a nutrient-enriched formula, demonstrating better growth (weight, length, and head circumference) among infants under 1,250 g at birth (2.75 lb). In a larger randomized trial conducted by Lucas and associates, preterm infants fed a nutrient-enriched formula were heavier and longer at 9 and 18 months corrected age. The effects were greater for preterm boys. No difference in neurodevelopmental outcomes was noted. These benefits were not exhibited if the nutrient-enriched formula was discontinued before

the preterm infant had reached at least 6 months corrected age. Infants who received enriched formulas until term or 2 months corrected age did not demonstrate any benefit. In a separate study by Koo and Hockman, very low-birth-weight, very preterm infants were fed a standard term formula or an enriched preterm formula. Among the infants enrolled in this study, a growth advantage at 1 year of age was noted for infants who were fed the standard term formula. However, details about the volume of study milk and amounts of other nutritional intakes were not recorded for the study subjects. It is possible that the increased energy needs were met by consuming larger volumes of term formula compared with the amount needed by infants consuming preterm formula.

The duration of feeding is an important consideration because most studies point out that the use of nutrient-enriched postdischarge formulas until the preterm infant is 6 to 12 months corrected age promotes better growth.

Postdischarge enriched formulas should be considered for feeding preterm infants, particularly those weighing less than 1,250 g at birth and other preterm babies who exhibit suboptimal catch-up postnatal growth. If used, enriched formula should be continued until the infant is 9 to 12 months corrected age. Preterm infants, such as those with significant chronic lung disease (CLD), higher metabolic needs, or poor postdischarge growth (slowing growth velocity or growth failure), may require continued specialized formula use beyond 12 months corrected age (Box 114-2).

If a standard formula is used at any time during the first 12 months after discharge in a preterm infant, supplemental vitamins and additional iron should be provided. Vitamin supplementation is recommended with a liquid multivitamin until the infant's intake reaches 600 mL/day (20 oz/day). If a postdischarge enriched formula is fed, supplemental vitamins may

### BOX 114-2 Preparation of Higher Caloric Density Preterm Formulas

Preterm Discharge Formulas (Enfacare/Neosure/Good Start Nourish)

1. Wash bottle with soap and water.
2. Rinse it with clean, cool water.

To make 24-calorie/oz formula:

- Measure **11 ounces of water** in a clear measuring cup.
- Add **6 level scoops of powder**. Only use the scoop that comes in your can of formula.

To make 24-calorie HUMAN milk:

- Measure **3 oz of human milk** in a clear measuring cup.
- Add **1 level teaspoon** of preterm infant formula powder. Use a teaspoon that comes in a measuring spoon set.

To make 27-calorie/oz formula:

- Measure **8 ounces of water** in a clear measuring cup.
- Add **5 level scoops of powder**. Only use the scoop that comes in your can of formula.

To make 27-calorie/oz HUMAN milk;

- Measure **3 oz of human milk** in a clear measuring cup.
- Add **2 level teaspoons** of preterm infant formula powder. Use a teaspoon that comes in a measuring spoon set.
- 3. Mix very well and pour into bottle(s).
- 4. Feed immediately or cover and refrigerate.
- 5. Throw out unused mixture after 24 hours.
- 6. Throw out any milk that is still in the bottle 1 hour after a feeding.

Supplements if additional calories are needed

Microlipid: 4.5 kcal/mL

Duocal: 42 kcal/Tbsp

MCT oil: 7.6 kcal/mL

Dry baby cereal: 10 kcal/Tbsp

not be necessary for infants whose intake is more than 200 mL/kg/day. Information about the composition, usage guidelines, and preparation of available post-discharge formulas and nutritional supplements is found in Chapter 112, Continuing Care of the Infant After Transfer From Neonatal Intensive Care. For children older than 1 year who continue to exhibit inadequate growth and weight of less than the 5th percentile for corrected age, nutritional supplementation can be continued using 1 of several specialized, complete formulas that provide 30 kcal/oz.

### Supporting Breastfeeding

Supplementation of infants who successfully transition to exclusive breastfeeding and demonstrate adequate weight gain and growth is not usually necessary. (See Chapter 88, Breastfeeding the Newborn.) Studies comparing preterm infants fed unfortified human milk or standard term formula after hospital discharge demonstrated lower bone mineral content, lower serum phosphorus, and higher serum alkaline phosphatase compared with preterm formula-fed infants. These differences persisted through 12 months of age, but by age 2, human milk-fed infants had caught up to their preterm formula-fed peers. Preterm infants who are exclusively breastfeeding should receive vitamin D and iron supplementation. Adequacy of growth should be closely monitored, with consideration given to supplementation with an iron-fortified standard term or enriched postdischarge preterm formula if an infant is exhibiting a slowing growth velocity or developing signs of nutritional deficiency. The physician should confirm that the infant is not experiencing hypoxemia or increased work of breathing during feeding because this may be contributing to suboptimal weight gain.

A suggested strategy to support continued breastfeeding, if growth is noted to be suboptimal, is as follows:

- Supplement exclusive breastfeeding every 2 to 3 hours during the daytime with formula feeding in the evening and during the night.

Alternatively,

- Enriched preterm formula can be mixed with expressed milk to increase the caloric density and nutrient composition as described in Box 114-2.
- Consider referral to a lactation specialist who has experience with preterm infants.

Supplementation should be continued for at least 6 months, or longer if the infant's growth and nutritional assessment have not normalized within that period. The goal is to achieve growth within the 25% to 50% range for corrected age. Some infants with poor growth, higher metabolic requirements, or specific nutritional deficiencies may need to remain on calorie-dense and nutrient-enriched feedings until 9 to 12 months corrected age. Periodic measurement of serum phosphorus and alkaline phosphatase is also important, given that phosphorus levels under 4.5 mg/dL and an elevated alkaline phosphatase above 1,000 IU/mL may warrant further evaluation and supplementation.

### Tube Feedings

Infants with chronic health conditions or neurologic impairment may not be able to tolerate a portion or all of their enteral feedings by mouth. In addition, infants

with specific nutrient or fluid requirements may require supplementation by tube feeding to ensure an appropriate intake. If tube feedings are necessary, the caregiver should ensure that the infant has opportunities for nonnutritive sucking either by sucking on a pacifier or through partial oral feeding. Some infants may require only episodic supplemental tube feedings until their oromotor skills mature. These babies may be able to have their feedings supplemented using a nasogastric (NG) tube if the parents are comfortable inserting it. Consideration should be given to placement of a gastrostomy tube in infants who are anticipated to require a longer period without full oral feeding (>3–6 months) because there are potential side effects of long-term NG feeding. Long-term tube feeding may be required for infants with neurologic or cardiorespiratory compromise, dysfunctional feeding, or other chronic health conditions. Side effects that may occur with long-term NG feeding include chronic nasal-pharyngeal-esophageal irritation, development of oral aversion, exacerbation of underlying gastroesophageal reflux, serous otitis media, incorrect placement of tube upon insertion, irritation of facial skin where tube is being taped, and rarely, perforation of the esophagus, lung, or stomach.

Infants who have gastrostomy tubes can experience problems caused by leakage or irritation and local infection at the gastrostomy insertion (stoma) site. Leakage may develop because of enlargement of the stoma site or inadequate inflation of the balloon that helps to keep the tube snug against the gastric wall. The amount of water in the gastrostomy balloon should be checked periodically (every 2 weeks); the balloon of an infant should typically contain 3 to 5 mL of water; an older child's balloon should be inflated with 5 to 10 mL of water, but these do vary depending on the individual manufacturer. During feeding, the infant should be positioned upright or right side down. Irritation, bleeding, and localized infection at the stoma site are common problems. Bleeding and irritation may arise as granulation tissue forms in response to tube movement. Applying a topical steroid or, if unsuccessful, cauterizing any granulation tissue that develops around the stoma may also reduce leakage. Localized fungal infections are not uncommon and respond to topical antifungal therapy.

Local care includes gently cleansing with mild soap and water 2 to 3 times per day; ensuring that the gastrostomy balloon is properly inflated and snug against the gastric wall; ensuring appropriate treatment of granulation tissue; and administering topical, systemic, or both forms of treatment of local infection. Tube migration may occur with slippage of the gastrostomy tube tip into the pylorus or duodenum. Measuring the tube and ensuring the external disk is secure against the abdominal wall reduce this risk. Accidental removal is more likely to occur in small infants and during the early weeks after initial gastrostomy tube placement, before complete healing has taken place. Parents can be instructed on how to replace a balloon gastrostomy that is mature (>4 weeks). If the family is uncomfortable replacing the tube themselves, they may be instructed to bring the child to the emergency department or physician's office. Mature gastrostomy tubes that become dislodged should be replaced within 24 hours.

### **Strategies to Support Tube Feeding and Transition to Oral Feeding**

Infants who are tolerating partial oral feeding (at least 50%) can be fed by mouth during the day as much as tolerated and tube-fed the remainder at night using either bolus or continuous feeds. If the presence of the NG tube causes increased gagging, consider removing the tube during the daytime to encourage oral feeding. If the infant does not seem hungry for oral feedings, consider adjusting the feeding volume or feeding interval to allow hunger cues to develop, ensuring that the infant's total daily intake is sufficient to meet nutrient, energy, and fluid needs.

If continuous feeds are given overnight, stop feeding at least 2 hours before the infant awakens in the morning to allow time for hunger cues to develop by the first morning feeding. Gradually decrease the amounts given at night to support increased appetite during the daytime.

When the oral intake is near the total required, discontinue tube feedings on a trial basis and monitor for weight changes. Temporary plateau in weight or loss of up to 5% may be acceptable for 1 to 2 weeks if the infant remains hydrated, well nourished, and otherwise healthy. If the child has a gastrostomy tube, it can be removed after an adequate period of monitoring on full oral feedings (at least 1 month).

### **Infants With Short Bowel Syndrome or Intestinal Failure**

Increased survival among neonates developing intra-abdominal emergencies has resulted in a higher prevalence of infants with short bowel syndrome requiring long-term nutritional support. Short bowel syndrome results from surgical resection, congenital defect, or disease-associated malabsorption with resultant loss of fluid, electrolytes, protein, and micronutrients. The range of clinical problems necessitating extensive bowel resection includes necrotizing enterocolitis, bowel atresia, midgut volvulus caused by a malrotation, and congenital intestinal aganglionosis. The loss of a significant portion of the intestines' absorptive capability can contribute to intestinal dysfunction or intestinal failure. Loss of absorptive function in existing intestinal tissue can cause intestinal failure and can develop following intestinal obstruction, dysmotility, intestinal resection, congenital defect, or disease-induced malabsorption. Infants with gastroschisis and markedly thickened bowel at delivery are at risk for developing intestinal failure. Infants who lose their ileocecal valve during surgery are at additional risk because the ileocecal valve slows intestinal transit time and prevents reflux of intestinal contents and bacteria from the colon into the small intestine. Associated complications include malabsorption of vitamin B<sub>12</sub>, bile salt deconjugation, reduction in bile salt absorption, and impaired intestinal function.

Management of short bowel syndrome and intestinal failure includes minimizing fluid, electrolyte, and nutrient losses, with the goal of promoting growth and optimal nutrition and maximizing the process of bowel adaptation. Long-term parenteral nutrition (PN) support through a secure central catheter is often required for these infants. Intestinal failure-associated liver disease occurs in 40% to 60% of infants with short bowel syndrome. Milder liver dysfunction in the form of

PN-induced cholestasis is also common in infants, with preterm infants at higher risk than term babies (see previous section). Infants on long-term PN support require care from a multidisciplinary team that includes pediatric surgeons, pediatric gastroenterologists, nutritionists, clinical nurse specialists, and home care nurses to assist the parents in caring for their child. When enteral feedings are initiated, continuous feedings through a gastrostomy tube are often the preferred method for feeding. In cases in which the infant has a mucous fistula, refeeding of the effluent from the proximal enterostomy into a distal mucous fistula has been shown to improve weight gain and maintain electrolyte stability. Additional important aspects of the infant's nutrition and intestinal rehabilitation include provision of non-nutritive sucking, oral-motor therapy, and early oral feedings, if feasible.

### **Feeding Problems**

Feeding difficulties are most common during the neonatal period but can remain a problem for preterm infants, as well as for babies who are recovering from severe cardiorespiratory or chronic lung disease, infants with neurologic impairments, and those with craniofacial or gastrointestinal malformations that may interfere with normal feeding. Additional factors that can contribute to feeding difficulties include tracheostomy, gastroesophageal reflux, and repetitive noxious oral stimuli caused by oral suctioning, repeated intubations, nasogastric or orogastric tube placement, and air flow from nasal cannula or nasal continuous positive airway pressure, which may result in feeding aversions. (The process of transitioning to oral feeding is discussed in Chapter 112, Continuing Care of the Infant After Transfer From Neonatal Intensive Care.) Delayed feeding skills may develop in infants who exhibit immature sucking and swallowing patterns, babies who experience frequent or prolonged illness or who fail to transition to age-appropriate feeding methods, infants with gastroesophageal reflux, or infants who are fed inappropriately (such as when force-fed). Oral reflexes that facilitate normal feeding and protect the airway from aspiration may be hypoactive or hyperactive. Tongue thrusting and a hyperactive gag reflex can further interfere with effective feeding. Infants who develop oral hypersensitivity (tactile defensiveness) may be unable to tolerate any oral stimulation and refuse placement of a nipple or spoon in their mouth. Dysfunctional feeding skills may develop in infants with physical, structural, or neurologic deficits, as well as infants with severe reflux. Babies who do not receive appropriate oral stimulation during enteral or parenteral feeding are also at risk. Feeding dysfunction may also develop after a fundoplication or surgical repair of a tracheoesophageal fistula. The primary care physician must recognize and intervene when feeding difficulties become apparent, especially when a persistent plateau in weight gain or poor growth occurs.

Referral for a feeding evaluation with a feeding therapist or interdisciplinary team should be considered if the parents or caregivers are reporting that feeding is stressful or difficult and any of the following is persistent:

- Feedings that consistently take longer than 45 minutes
- Feeding more frequently than every 2.5 to 3 hours resulting from infant fatigue, food refusal or

avoidance behaviors, or difficulty achieving an adequate feeding volume

- Parent needing to enlarge or cut a nipple hole for the infant to suck human milk or nonthickened formula successfully from the nipple
- Parents reporting that the only way the infant will complete a bottle is during sleep
- Parents having difficulty interpreting or responding appropriately to the infant's cues
- Disrupted sleep associated with crying or a parental perception of the infant being in pain
- The infant exhibiting significant discomfort during or for 30 minutes after feeding, including
  - Arching, grimacing, grunting, leg stiffening
  - Multiple swallows, coughing, emesis
  - Significant loss of fluid during feeding, poor lip seal, wide jaw excursion

- Heavy breathing or nasal flaring
- The need for frequent rest periods or pacing during feeding

Among infants who are unable to orally feed because of oromotor coordination difficulties or aspiration risk, the goal of feeding therapy is to attempt to normalize oral sensorimotor development and to develop protective reflexes and oral motor skill. Oromotor difficulties and aspiration risk can be further evaluated with a modified barium swallow study, which may help to direct the approach taken by a feeding therapist. Infants with significant feeding issues who are otherwise typically developing remain at risk for later communication disorders involving expressive language. Box 114-3 outlines a series of anthropometric, clinical, feeding, and dietary “red flags” that should alert the physician to the need for

### BOX 114-3 Anthropometric, Clinical, Feeding, and Dietary “Red Flags” for High-Risk Infants

#### ANTHROPOMETRIC

- Weight for age or weight for length <5% on the standard CDC growth chart for corrected age
- Weight for age or weight for length >95%
- Slowing growth velocity, weight loss, or significant decline in percentiles, especially if decline in weight percentile precedes decline in length
- Poor weight gain for age, adjusted for prematurity up to 24 mo of age
  - Term (40 wk PMA) to 3 mos: <20 g/day (<5 oz/wk)
  - 3 to 6 mo: <15 g/day (<3.5 oz/wk)
  - 6 to 9 mo: <10 g/day (<2 oz/wk)
  - 9 to 12 mo: <7 g/day (<1.5 oz/wk)
  - 1 to 2 yr: <1 kg (2 lb)/6 mo
  - 2 to 5 yr: <0.7 kg (1.5 lb)/6 mo
- Disproportionate head growth
  - Term to 3 mo: <0.5 cm/wk
  - 3 to 6 mo: <0.25 cm/wk
  - Any time during infancy: >1.25 cm/wk

#### CLINICAL

- Vomiting
- Diarrhea
- Constipation
- Chronic health conditions
- Chronic medication use that can affect nutritional status

#### FEEDING

- Use of technology to support nutrition
  - Gastrostomy tube, nasogastric or jejunal tube feeding
  - Supplemental feeding systems or lactation aids
  - Home parenteral nutrition
- Parents have difficulty interpreting or responding appropriately to feeding cues

- Prolonged feeding duration, insufficient intake, or difficulty with feeding or food progression

#### INFANTS

- More than 30 min to complete a feeding
- Fussy or distressed during feeding
- Respiratory distress during feeding
- Difficult to wake for feeding
- Feeding fatigue
- Frequently gags, coughs, or chokes during feeding
- Refuses feeding or arches backward during feeding
- Limited intake
  - Fewer than 5 feedings/day or less than 24 oz/day
  - Older than 6 mo corrected age not yet starting spoon feeding (persistent tongue thrusting, oral sensitivity)

#### TODDLERS

- More than 45 min to complete a meal
- Inappropriate intake
  - Fewer than 4 feedings/day or less than 16 oz milk/day with no other sources of dietary dairy products
  - Older than 1 yr drinking more than 32 oz cow milk/day
  - Older than 1 yr not taking finger foods
- Limited dietary intake—exclusion of 1 or more food groups
- Mealtimes are frustrating for parent or child or both
- Inappropriate formula preparation or use
  - Low iron formula
  - Using enriched preterm formulas for nonrecommended purposes
  - Adding inappropriate supplements to infant formula or breast milk
  - Adding insufficient or excess water during infant formula preparation (overfeeding: more than 40 oz/day)

CDC, Centers for Disease Control and Prevention; IHDP, Infant Health and Development Program; PMA, postmenstrual age.

Adapted from Groh-Wargo S, Thompson M, Cox JH, eds. *Nutritional Care for High-Risk Newborns*. 3rd ed. Chicago, IL: Precept Press; 2000. Used by permission.

evaluation of the infant's feeding ability and appropriateness of the nutritional intake. Sample questions to assist the provider in assessing the infant's feeding proficiency are provided in Box 114-4.

Feeding an infant is normally a relaxing, nurturing act that plays a role in parent-infant bonding. In the presence of a feeding disorder, feedings may become a major source of stress, frustration, and anxiety for the infant, parent, and physician; thus, early recognition of these issues is essential.

### Management of Regurgitation

Regurgitation is common among infants and must be distinguished from the potentially more serious gastroesophageal reflux disease. Strategies for the management of infants with significant gastroesophageal reflux have been published by the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition and are summarized in Chapter 112, Continuing Care of the Infant After Transfer From Neonatal Intensive Care. (See also Chapter 255, Gastroesophageal Reflux Disease.) Techniques to manage the common effects of regurgitation are based on symptom reduction or symptom control. Infants who are vomiting as a result of overfeeding benefit from smaller, more frequent feedings. If the infant is not gaining adequate weight, increasing the caloric density of the infant's formula can promote weight gain without the need to increase the feeding volume. Reduction of air swallowing before or after feeding can be controlled by starting the feeding before the infant cries for a prolonged period. Use of an angled bottle or positioning the bottle so that the nipple is filled will reduce the amount of air swallowed. Proper positioning of the baby and cheek support are recommended to ensure that the infant grasps the nipple correctly and is able to maintain good lip closure on the nipple. Avoiding excessive stimulation during and after feeding is another effective strategy to limit vomiting. Prone positioning is no longer recommended unless

the infant is continuously monitored. Use of hyperosmolar formulas ( $\geq 27$  kcal/oz) or fat supplements should be avoided because these forms of caloric supplementation can delay gastric emptying.

### Constipation

Constipation is common in premature infants. Factors that contribute to difficulty with stooling include decreased abdominal muscle strength and intestinal motility, decreased free water intake from nutrient-dense feedings, an increased incidence of mechanical gastrointestinal dysfunction after episodes of necrotizing enterocolitis or other gastrointestinal complications, and an increased incidence of muscle tone abnormalities associated with preterm birth or significant illness. A thorough examination is also important to evaluate the infant for the presence of anterior anal displacement, an anatomic cause of constipation. Dietary manipulation to provide more fiber (non-rice-containing cereal, strained prunes or prune juice, pears or apricots, spinach) can be tried for infants older than 4 months corrected age who are tolerating complementary feedings. Milk of magnesia and osmotic laxatives such as a malt soup extract, polyethylene glycol, and lactulose can be considered in the treatment of uncomplicated constipation in older infants. Mineral oil should be avoided in children younger than 2 years or if the child has lung disease or swallowing problems because of the risk for aspiration. Consultation with a pediatric gastroenterologist should be considered for infants with persistent symptoms to rule out any anatomic abnormalities.

### Introduction of Solid Foods

Introduction of solid foods into the diet of the high-risk infant will depend on several factors, in particular the infant's readiness and ability to accept complementary foods by mouth. In general, introduction of solid foods can begin at 4 to 6 months corrected age, provided that the infant exhibits appropriate postural control of the head, neck, and trunk; decreased tongue thrusting; and an interest in feeding. Although some preterm infants with sucking difficulty may prefer feeding solids by spoon, others may exhibit difficulty tolerating the thickened texture of solid food or demonstrate aversive responses to the forms of oral tactile stimulation associated with spoon feeding. So as not to interfere with the adequacy of formula intake, a general rule of thumb to offer parents is to hold off on the introduction of solid foods until the infant is consuming between 28 and 32 ounces of formula per day. Recent studies have suggested that breastfed infants benefit most from introducing meats as the first solid food because they are rich in iron, which is diminishing during the second half of the first year. Meats are good sources of high-quality protein, iron, and zinc and provide greater nutritional value than cereals, fruits, or vegetables.

### Catch-up Growth

Most catch-up growth occurs during the first 2 to 3 years of life, with a significant growth spurt between 36 and 40 weeks postmenstrual age. As discussed in Chapter 115, Health and Developmental Outcomes of Very Preterm and Very Low-Birth-Weight Infants,

#### BOX 114-4 Sample Feeding Questions

- Is feeding your baby unusually stressful?
- How much time does it take to feed your baby?
- Is there any dribbling of milk down your baby's chin while he/she is feeding?
- What type of nipple are you using?
- Have you made any changes or modifications to the nipple or the baby's feeding routine since the baby has come home?
- Does the baby seem uncomfortable during or after the feeding? Does he/she cry or arch frequently? What about vomiting or spitting up?
- Does the baby suck a pacifier? If so, can he/she keep it in his/her mouth by himself/herself while sucking? (If not, this suggests low oromotor tone or oral tactile sensitivity or both.)

very low-birth-weight children often remain lighter, shorter, and with smaller head size through early to middle childhood.

Head growth is usually more rapid than weight gain and is often the first parameter to catch up. Rapid head growth must be distinguished from pathologic head growth caused by late-onset hydrocephalus and may require neuroimaging to ensure that progressive ventriculomegaly is not developing. Some infants exhibit head growth that crosses head circumference percentiles, but this growth should rarely exceed the 97th percentile. Often, increased extra-axial fluid (subarachnoid) can be a benign cause for this increase, noted as a head circumference greater than the 95th percentile between 3 and 12 months corrected age, which then plateaus rather than continuing to increase. However, in some cases this may not be benign and may be associated with an increased risk for future developmental delays. The head circumference should be measured at each visit during infancy. Cranial imaging is required if the rate of head growth is more than 1.25 cm/week or if any signs or symptoms are noted of increased intracranial pressure or changing neurologic status. Suboptimal brain growth, reflected in a head circumference declining more than 2 standard deviations below the mean, increases the infant's risk for developmental delays. Growth velocities for weight and length vary significantly, and an increase in weight may precede an increase in length. Growth velocity may fluctuate as the infant increases activity levels, experiences an intercurrent illness, or has feeding difficulty, worsening reflux symptoms, or changes in diet and caloric intake. Low weight for length or a decline in all growth parameters suggests inadequate nutritional intake. Obesity may also develop in infants who were preterm or who experienced poor weight gain while in the hospital. Parents become hypervigilant about feeding and food intake or may be unable to read their infant's cues, interpreting crying and fussiness as signs of hunger. Such issues can lead to overfeeding the infant.

### **Small-for-Gestational-Age Infants**

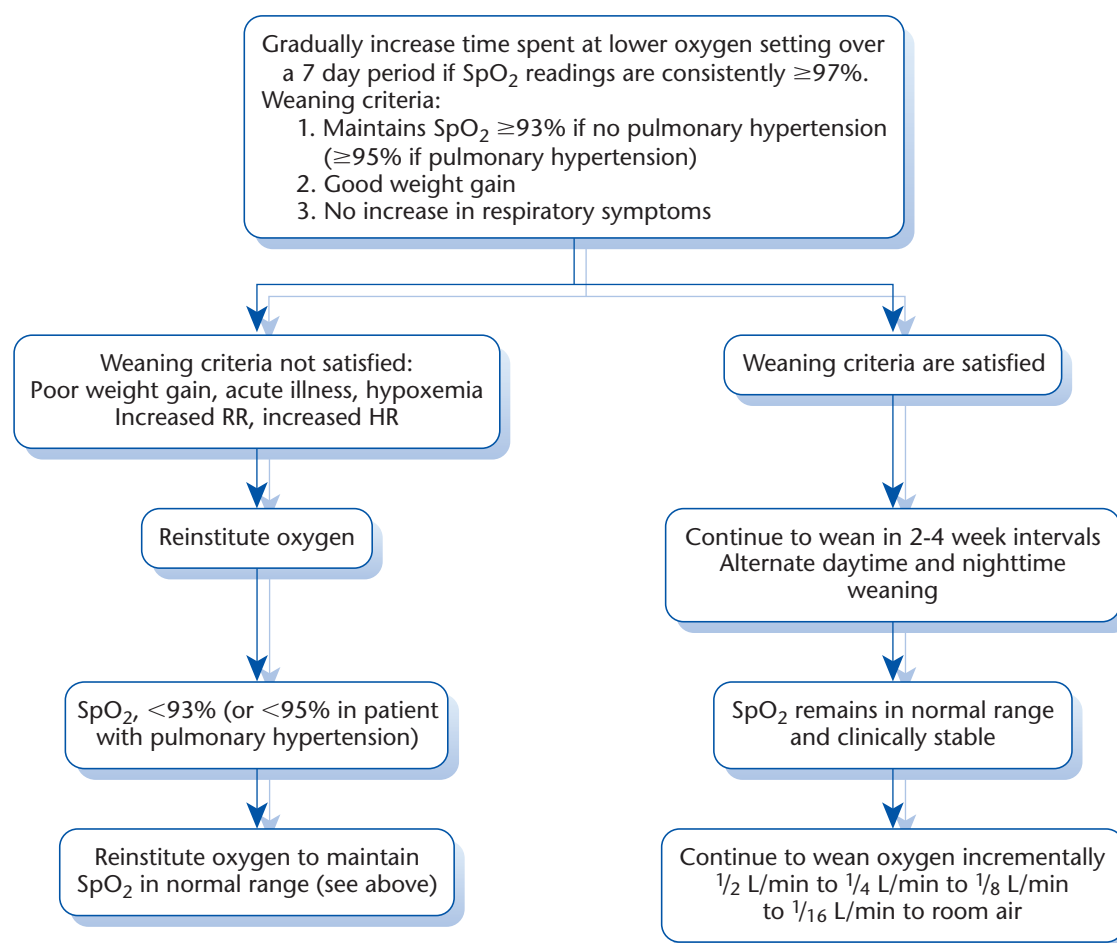

Growth potential for infants born small for gestational age (SGA) depends on the underlying cause of the fetal growth abnormality and is most likely to be limited for specific infants who are less than the 3rd percentile for gestational age at birth. Seventy percent to 80% of SGA children will exhibit catch-up growth during the first years of life. Investigations are ongoing about the potential benefits of hormonal therapy (growth hormone) for the 10% of SGA children who do not exhibit catch-up growth. In a 2007 consensus statement, the International Societies of Pediatric Endocrinology and the Growth Hormone Research Society recommend that SGA children who do not demonstrate catch-up growth should be referred for early monitoring, evaluation for possible endocrine and metabolic disturbances, and neurodevelopmental assessment for potential delays warranting early intervention. Consideration of early therapy with growth hormone should be given to children between 2 and 4 years of age whose height remains more than 2.5 standard deviations below the mean for age.

### **Chronic Lung Disease**

Chronic lung disease (CLD), which includes bronchopulmonary dysplasia (BPD), is a significant health condition affecting many graduates of neonatal and pediatric critical care. BPD/CLD refers to unresolved lung disease following acute lung injury in the neonatal period. Discussion about pathogenesis, pathophysiologic features, and early management strategies can be found in Chapter 112, Continuing Care of the Infant After Transfer From Neonatal Intensive Care; Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn; and Chapter 113, Discharge Planning for the High-Risk Newborn Requiring Intensive Care. Many infants continue to have symptoms after discharge home from the hospital and may episodically exhibit the following signs: tachypnea and tachycardia, paradoxical respirations (see-saw pattern during wakefulness), retractions, cough, wheezing, pallor or cyanosis, irritability or lethargy, poor feeding, and poor weight gain or weight loss. Additional conditions that can further exacerbate CLD symptoms include gastroesophageal reflux, upper airway obstruction caused by tracheomalacia, bronchomalacia, or subglottic stenosis; acute, intercurrent infections; high altitude for infants residing well above sea level; and poor compliance with home oxygen, bronchodilator, or diuretic therapy. Optimal management for the infant with CLD involves a combination of strategies aimed at optimizing the infant's nutrition, respiratory treatment (oxygen, medications), avoidance of infection or exposure to secondhand smoke, and parental education to support and optimize the child's care. Figure 114-1 provides a sample algorithm for weaning home oxygen therapy. Box 114-5 describes strategies to optimize the care of children with CLD.

If the infant is discharged home on diuretics, then the question arises as to when these medications can be weaned or when the infant can be permitted to outgrow the discharge medication dose. The diuretics can be weaned if the infant remains clinically well, exhibits adequate weight gain, has no evidence of respiratory distress, and has an improved lung examination. The lung fields should be clear to auscultation, with a heart rate and respiratory rate that remain in the normal range for the infant's age. The infant should not have any evidence of hepatomegaly (because of heart failure or lung hyperinflation), should be weaning from or stable on supplemental oxygen, and should have no signs of fluid retention.

Infants who have difficulty weaning from supplemental oxygen should be evaluated for adequacy of their caloric intake because their energy and nutrient needs may have increased. Medication doses should be reviewed and doses adjusted for weight gain. Consideration should also be given to adding medications depending on symptoms. Consultation with a pediatric pulmonary specialist can assist the PCP in optimizing the infant's respiratory care. The infant's history should be reviewed to determine whether new or worsening reflux symptoms or signs of aspiration are present. The infant's oxygen saturation should be checked in all activity states and the oxygen concentration adjusted to maintain the oxygen saturation at

**Figure 114-1** Weaning home oxygen therapy. *HR*, heart rate; *RR*, respiratory rate.

### BOX 114-5 Strategies to Optimize Care of Infants With Chronic Lung Disease

#### RESPIRATORY

- Oxygen saturation should be maintained higher than 92% to 93% for infants with bronchopulmonary dysplasia (but without pulmonary hypertension)
- During sleep, the oxygen saturation (measured using pulse oximetry) should be kept above 93% because this has been shown to improve sleep architecture
- Infants who have evidence of pulmonary hypertension should be maintained at a target range of 94% to 96%<sup>a</sup>
- Infants should be closely monitored for illness and acute or subtle signs of hypoxemia or bronchospasm
- May need to increase or reinstitute oxygen therapy
- May need to initiate or increase the frequency of bronchodilators or corticosteroids

#### MEDICATIONS

- Diuretics: try to wean off as soon as possible after discharge
- Hydrochlorothiazide: 20 to 40 mg/kg/day divided 2 to 3 times per day
- Spironolactone: 2 to 4 mg/kg/day divided every 12 hr (if needed to offset electrolyte imbalance)
- Potassium chloride: 1 to 4 mEq/kg/day divided every 6 to 12 hr (if electrolyte imbalance noted)
- Bronchodilators: used if there is a component of reversible airway obstruction and recurrent symptoms (tachypnea, cough, or wheeze); avoid chronic use
  - Albuterol: 0.5 to 2.5 mg (0.1–0.05 mL) by nebulizer or 90 to 180 mcg (1–2 puffs) by metered dose inhaler every 4 to 6 hr

**BOX 114-5 Strategies to Optimize Care of Infants With Chronic Lung Disease—cont'd**

- Ipratropium bromide: 250 to 500 mcg ( $\frac{1}{2}$ –1 vial) by nebulizer or 18 to 36 mcg (1–2 puffs) by inhaler 20 min before albuterol (if not stabilized on  $\beta$ -agonist alone).
- Levalbuterol: 0.62/3 mL to 1.25 mg/3 mL solution by nebulizer or 1 to 2 puffs inhaler (45 mcg/actuation) every 4 to 6 hr used in lieu of albuterol (if side effects noted from albuterol)
- Anti-inflammatory drugs
  - Inhaled nonsteroidal: cromolyn sodium: 20 mg (2 mL) by nebulizer or 1,600 mcg (2 puffs) TID (2–4 wk required for adequate trial)
  - Inhaled steroids (side effects minimized by use of a spacer device)
    - Budesonide: 0.25–0.5 mg every 12–24 hr
    - Fluticasone: 44 mcg/puff (1–2 puffs) every 12 hr up to 110 mcg/puff (1 puff BID)
    - Beclomethasone: 40 to 80 mcg/puff (1–2 puffs) every 12 hr
  - Oral prednisone for serious acute exacerbations: 2 mg/kg initial dose, then 1 mg/kg every 12 hr for 5 days (starting 12 hr after initial dose)

**PREVENTION OF INFECTION AND REACTIVE AIRWAYS DISEASE**

- Respiratory syncytial virus and influenza virus prophylaxis
  - Avoid secondhand smoke and vapor exposures: paint, kerosene, strong perfumes, aerosol sprays, incense, fireplace smoke, or soot
  - Limit exposure to crowds and large child-care settings
  - Hand washing

**OXYGEN THERAPY**

- Can be weaned to a lower oxygen concentration (lower flow rate) when oxygen saturations are routinely  $>97\%$  and when the infant exhibits: (see Figure 114–1)
  - No symptoms of respiratory distress or decreased stamina

- Sustained, adequate weight gain
- No recent intercurrent illnesses and improving overall health status
- The ability to maintain oxygen saturation at or above 95% after 30 to 40 min on the proposed lower oxygen setting without any increase in respiratory symptoms. Close monitoring for several days to assure stable oxygen saturations
- No compensatory tachypnea, tachycardia, pallor, cyanosis, or respiratory distress
- No change in activity level, endurance, or increase in irritability

**FEEDING AND NUTRITION**

- Provide adequate calories to promote a weight gain of 15 to 30 g/day; to realize catch-up growth, weight gain of 45 to 60 g/day may be necessary
  - Increased calorie requirements resulting from increased work of breathing and greater calorie consumption
  - Infants often need 120 to 150 kcal/kg/day
  - Use nutrient-dense feeding, providing 22 to 26 kcal/oz (increasing further by adding carbohydrate and/or fat supplements) with close monitoring of fluid and electrolyte status; for children older than 1 yr, there are nutritionally complete formulas that provide 30 kcal/oz
  - Infants with moderate to severe chronic lung disease may require fluid restriction; attention is needed to provide appropriate calories without giving an excessive solute load that can cause additional complications
  - Consider tube feeding to supplement oral feeding if inadequate weight gain occurs with oral feedings alone
  - Closely monitor the infant for signs of feeding difficulties and initiate early referral for feeding therapy if appropriate
- Infants with signs of gastroesophageal reflux disease should be treated aggressively

\*Abman SH. Monitoring cardiovascular function in infants with chronic lung disease of infancy and childhood. *Am J Respir Crit Care Med.* 2003; 168(3):356–396.

From Panitch H. Bronchopulmonary dysplasia. In: Libby RC, Imaizumi SO, eds. *Guidelines for Pediatric Home Health Care.* 2nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2009:317–344.

or above 92% to 93%. The infant should be screened for significant anemia that may be contributing to symptoms. Additional testing can include a chest radiograph, an electrocardiogram, and possibly an echocardiogram to evaluate for worsening pulmonary disease (atelectasis or infiltrates) or cardiovascular sequelae (pulmonary hypertension, right ventricular heart failure/cor pulmonale) associated with progressive CLD. A blood test for B-type natriuretic peptide can be of additional benefit in assessing degree of right heart failure.

**Infants Discharged on Home Monitoring**

Home cardiorespiratory monitoring may be required for infants with persistent apnea or apparent life-threatening

events, those discharged home on supplemental oxygen or methylxanthines, and babies with chronic conditions or malformations that impair cardiorespiratory function. If home monitoring is prescribed, an event recorder monitor capable of data storage (memory) should be used. The parents and all caregivers of infants discharged on home monitoring should have CPR training as well as be educated on how to respond to alarms before discharge. Within 1 week after discharge, follow-up contact with staff from the home monitoring program should occur. Subsequent follow-up contacts are often within 2 to 4 weeks and may entail a visit to the apnea center or communication by phone. Depending on the reason for home monitoring, many physicians will discontinue monitoring after a symptom-free period of 4 to

6 weeks (best documented by a monitor download); some physicians will obtain a monitor download (performed at home) or refer the infant for a diagnostic sleep study to assess the infant for any evidence of central or obstructive events that warrant continued therapy, monitoring, or both. If the infant has an abnormal study 4 to 6 weeks after discharge, monitoring can be continued for an additional 4 to 6 weeks, followed by repeat testing for persistent abnormalities. If a preterm infant is discharged on a methylxanthine, such as caffeine, the medication may be discontinued when the infant reaches term gestation, provided that the baby is not having any symptoms or monitor alarms. A monitor recording or polysomnographic study should be obtained 7 to 14 days after discontinuing the medication. If the study is normal, then monitoring can be safely discontinued. If the study is abnormal, monitoring should be continued. The decision whether to reinstitute methylxanthine treatment is typically based on the severity of abnormalities documented on the recording.

### Outpatient Screening

Follow-up care for high-risk infants should include periodic screenings beyond the components of care that are routine for full-term infants based on the infant's chronic conditions and risk factors.

### Hearing Screening

Continued surveillance and periodic hearing testing are necessary for infants at risk for delayed-onset or progressive hearing loss. Infants who fail or miss NICU hearing screening must have follow-up testing scheduled. Infants with known hereditary (genetic) or acquired conditions associated with a high risk for hearing loss should be referred for medical evaluation and comprehensive audiologic and otologic evaluation. Factors to consider when determining the frequency of periodic hearing testing, beyond parental concern, include a family history of permanent hearing loss or a syndrome with associated hearing loss, the need for intensive care for more than 5 days or assisted ventilation longer than 10 days, and prolonged exposure to ototoxic medications (aminoglycosides such as gentamicin and tobramycin) or loop diuretics (furosemide). Infants who have recovered from postnatal infections associated with sensorineural hearing loss, including bacterial meningitis and in utero infections such as cytomegalovirus, herpes, rubella, syphilis, or toxoplasmosis, also require serial hearing testing. Babies treated for severe hyperbilirubinemia (those requiring an exchange transfusion) or who experience respiratory failure necessitating extracorporeal membrane oxygenation are also at high risk for progressive or late-onset hearing loss and should have follow-up hearing tests every 6 months until 3 years of age.

### Ophthalmologic Examinations

Follow-up of preterm infants with retinopathy of prematurity (ROP) should adhere to the screening and surveillance guidelines issued by the American Association of Pediatric Ophthalmology and Strabismus and the American Academy of Ophthalmology

in collaboration with the AAP. The frequency of surveillance is based on the examining ophthalmologist's findings. The Canadian Association of Pediatric Ophthalmology and the United Kingdom have similar guidelines regarding the timing of initial screening and subsequent surveillance. The risk for vision loss from ROP is low after the preterm infant has reached 45 weeks postmenstrual age without developing prethreshold or more severe ROP, if the infant's retina is vascularized into zone III without evidence of retinopathy in zone II, or if the retina is fully vascularized. At this point, serial ROP screening can be discontinued. However, periodic surveillance of visual acuity and other ocular morbidity should continue. Preterm infants should be examined by a pediatric ophthalmologist at 6 and 12 months corrected age, before school entry, and again at 9 to 12 years of age. Robaei and colleagues recently reported on visual morbidity affecting moderately preterm and low-birth-weight children who were born between 32 and 36 weeks' gestation, weighing between 1,500 and 2,499 g. Both groups of children were found to be at higher risk for development of amblyopia, strabismus, and decreased visual acuity. Low-birth-weight children were also more likely to exhibit anisometropia.

### Neurodevelopment and Behavior

Neurologic immaturity, sensory defensiveness, and transient muscle tone abnormalities can cause concern for families caring for preterm babies and infants recovering from serious illness. Strategies to support these infants' ability to tolerate stimulation and handling include using calming techniques, using containment positioning during holding and especially bathing, and cautioning parents against infant swing use because this causes sudden changes in movement patterns. Calming techniques consist of swaddling and containment (ie, holding the infant with arms and legs flexed close to the body). The infant should be swaddled or positioned using containment before being moved. Sudden movements should be avoided. Pacifiers can be helpful for infants who have an organized sucking response and are receptive to the pacifier. Family members must be made aware of the early developmental needs of the infant recovering from a very preterm or traumatic birth. Infant sleep should be protected to promote development and infant regulation. Recognizing and responding to the infant's neurodevelopmental cues can help the infant's adaptation to the environment and support the infant's increasing tolerance of handling and other forms of sensory stimulation. Parents benefit from guidance about their infant's ability to signal their needs through movement, facial expressions, and breathing patterns, and about how to interpret and respond to these behavioral cues. Some neonatal units have therapists or psychologists trained in the NIDCAP (Newborn Individualized Developmental Care and Assessment Program), an assessment performed with parent participation at the bedside that highlights the strengths and weaknesses of the infant. These sessions can help to teach parents about their child and make recommendations on

how to encourage continued developmental progress. During the early weeks and months after hospital discharge, preterm infants may be more irritable and less responsive to their environment and social interactions. They typically need more help in calming and learning to self-soothe. The primary goal of caregiving is to match the caregiver's responses to the infant's needs without being intrusive or overwhelming the infant. Consistent caregiver responses to the infant's cues help the infant learn to anticipate and expect a response. Exposure to electronics such as television and handheld devices should be avoided before 2 years corrected age.

As the infant matures and recovers, parents' concerns about infant vulnerability can affect their parenting skills and contribute to child behavior problems over time if they have difficulty with limit setting and discipline. Symptoms of posttraumatic stress disorder (PTSD) are increased for parents of NICU graduates, and the hypervigilance that is a hallmark of PTSD can contribute to parental overprotection. Overprotective behaviors can result in infant sleep disruption and interfere with normal infant exploration, which plays a key role in development. Parents will benefit from support and guidance about strategies to encourage appropriate infant development. Often, support can come from therapists within early intervention programs serving infants birth to age 3 years or interdisciplinary professionals associated with follow-up programs. Many families will consult baby books and multimedia resources and search the Internet for information and guidance about their infant's particular health issues and routine aspects in infant care. Parents should be reminded to adjust for their infant's prematurity when reading information about anticipated growth and development. Families will also benefit from assistance, available from their PCP, early intervention therapist, or interdisciplinary professional, with sorting through the myriad materials in press, in the media, and on the Internet to discern factual information.

### Family Adjustment

The stress of a preterm or sick newborn can have serious effects on parents and siblings, cause significant economic hardship, and lead to family disruption and dysfunction. Parents often feel isolated and experience a wide range of emotions ranging from euphoria to despair. Discord may develop between the parents, or between the parents and other family members or members of the infant's medical team. Each parent and family member has unique coping abilities, values, beliefs, and preferences. Grandparents, extended family members, and friends can be a source of emotional support and respite for the parents. The converse may also occur when parental perspectives and wishes differ from the values and beliefs of other family members or friends. Siblings may be or feel neglected and may exhibit behavioral changes caused by disruption in the family routine and associated parent distraction and distress. Child vulnerability (vulnerable child syndrome) is discussed in Chapter 115, Health and Developmental Outcomes of Very Preterm

and Very Low-Birth-Weight Infants, and Chapter 116, Health and Developmental Outcomes of Selected Medically Complex Neonates. All the typical concerns of parents of healthy infants are exaggerated when the child is born prematurely or with a birth defect, or has experienced significant neonatal illness. Parents should be encouraged to normalize their care routines for their preterm or recovering infant as much as possible. Having opportunities to connect with other families of similar children is helpful for families who have a premature or sick infant because they can gain insight and support from their shared experiences. A subset of parents of preterm infants will experience serious symptoms of anxiety, post-traumatic stress, or depression that extend well beyond the neonatal period. These symptoms are known to have a significant detrimental effect on parent-child relationships and child development. The likelihood of parents developing these more lasting mental health concerns is not necessarily directly related to the severity of the infant's medical course, and predisposing parental factors play a significant role in determining risk. In these cases, parents will benefit from psychological or psychiatric intervention. There are several mental health screening tools available for use in primary care. See [www.integration.samhsa.gov/clinical-practice/screening-tools](http://www.integration.samhsa.gov/clinical-practice/screening-tools) for a sample. Guidance on assisting families who are confronting an unfavorable diagnosis or chronic illness for their infant is found in Chapter 9, Partnering With Families in Hospital and Community Settings, and Chapter 67, Palliative Care and Bereavement.

If developmental concerns become apparent or persist beyond age 3 years, referral can be made for an evaluation in the federally mandated 3- to 5-year-old assessment programs that are administered by the county or school district of residence. Those caring for a child who is struggling in any developmental domain, including a physician, nurse, therapist, or family member, can ask for such an evaluation. Given the higher rates of learning disabilities, attention-deficit/hyperactivity disorder, emotional and behavioral disorders, and autism in this high-risk population, these evaluations can be quite helpful in identifying any problems that may need intervention well before official school age or put a parent's mind at rest if, in fact, the child is developing within the normal range for their age.

## SECTION FIVE

# Neonatal Outcomes

### Chapter 115

## HEALTH AND DEVELOPMENTAL OUTCOMES OF VERY PRETERM AND VERY LOW-BIRTH-WEIGHT INFANTS

Deborah E. Campbell, MD; Sonia O. Imaizumi, MD;  
Judy C. Bernbaum, MD

Approximately 10% to 15% of newborns require specialized neonatal care after their birth. The preterm and low-birth-weight (LBW) rates in the United States increased through 2006 and were reported as 12.8% and 8.6%, respectively. Since 2006, preterm and LBW rates have steadily declined in the United States to 11.6% and 8% respectively. In 2012, 3.4% of babies were born before 34 weeks' (34<sup>0</sup>/<sub>7</sub>–34<sup>6</sup>/<sub>7</sub> weeks) gestation and 8.1% were born 34 to 36 weeks' gestation. Most of the reduction in preterm and low-birthweight deliveries has been among infants born late preterm ( $\geq 34$  weeks' gestation) and in the rate of triplet and higher-order multiple births. Modest reductions in preterm birth rates have been seen among non-Hispanic black (11%), non-Hispanic white (10%), and Hispanic women (5%).

Innovations in prenatal diagnosis, fetal interventions, and neonatal intensive and surgical care have contributed to the survival of extremely premature babies and infants with malformations for which therapy was previously limited. Improved survival rates have led to increased numbers of infants and children with chronic health conditions and increased use of chronic and acute care resources. The need for neonatal intensive care after birth has long-term health-related quality-of-life (HRQL) implications. This need is particularly present for children born preterm. Rehospitalization rates for infants who have required neonatal intensive care are higher than for healthy term infants. Illness is typically less severe among late preterm infants (greater than 34 weeks' gestation) and babies who required fewer than 4 days of neonatal intensive care. As discussed in Chapter 90, Care of the Late Preterm Infant, babies born between 34 and 36 completed weeks of gestation are most likely to require rehospitalization for problems related to jaundice, feeding difficulties, dehydration, and suspected sepsis. Among infants younger than 32 weeks' gestation, the most common readmission diagnoses are sepsis, respiratory disease, gastroesophageal reflux or apparent life-threatening events, and hernia repair. Normal-birth-weight (NBW) infants who require neonatal intensive care, babies with congenital anomalies, and neonates with a low 5-minute Apgar score have

higher post-neonatal intensive care unit (NICU) health care utilization—physician visits, assistive technology use, and rehospitalization; over 30% of infants with malformations require rehospitalization during the first 6 months of life.

The primary causes of postneonatal deaths for infants between 28 and 365 days of age have remained stable over the last decade, although the number of infants dying during the postnatal period from a specific cause has changed. During 1985 and 1986, the most common causes for postneonatal death were sudden infant death, congenital conditions, prematurity-related conditions, and nonintentional injuries. The Centers for Disease Control and Prevention reported that the 5 leading causes of infant mortality during 2011 were congenital malformations (20%), disorders relating to short gestation and LBW (16%), sudden infant death syndrome (8%), maternal complications of pregnancy (6%), and unintentional injuries (4%). The frequencies of these causes of death also vary by geographic region in the US, as well as by race and Hispanic origin.

### HEALTH-RELATED OUTCOMES DURING INFANCY AND CHILDHOOD

Health-related outcomes and HRQL are important considerations when evaluating the consequences of neonatal illness and the cost effectiveness of care. Infancy and early childhood measures of quality of life and health status among newborns requiring neonatal intensive care reveal that preschool-aged children who required NICU care had poorer health status and HRQL than newborns who did not require NICU care. Among preterm children born at less than 32 weeks' gestation, parents report significantly lower HRQL, with problems affecting the lungs and stomach, feeding disorders and problems with motor functioning, communication problems, and anxiety. The range and severity of the developmental and health conditions experienced by these infants is influenced by the number of developmental domains affected. Among infants tracked prospectively who were born at less than 30 weeks' gestation, 17% had a single disability, whereas 44% exhibited multiple disabilities. Low birth weight, chronic lung disease (CLD), and evidence of disability at 2 years were associated with multiple impairments. Health outcomes and HRQL of preschool children born between 29 and 32 weeks' gestation have been shown to be quite similar to those of children born at less than 28 weeks' gestation, despite the fact that the children born earlier than 28 weeks' gestation typically are sicker than the later-arriving group of infants. In addition, children born at 28 to 32 weeks' gestation differ in both health and development in

comparison to children born at term. Among children with intellectual disability, the prevalence of birth defects is reported to be approximately 30% in population-based data, the percentage of intellectual disability varying with the specific organ system involved. Among moderately preterm infants, born at 32 to 33 weeks of gestation, poorer health, developmental, and school age performance outcomes than their full-term, NBW peers are also common. A comprehensive review of outcomes for all infants requiring neonatal special or intensive care is beyond the scope of this chapter. However, outcomes are reviewed for the broad categories of infants who require the greatest resource utilization while hospitalized.

### Respiratory Disease and Lung Function

Chronic lung disease of infancy encompasses a heterogeneous group of pulmonary disorders that originate in the perinatal period and produce airway and parenchymal inflammation leading to chronic airway obstruction, increased work of breathing, and airway hyperreactivity. Bronchopulmonary dysplasia (BPD) is one such condition that develops in response to the interplay of inciting factors: lung immaturity and surfactant deficiency in combination with barotrauma and stretch injury to the lung and oxygen toxicity from the therapies applied to treat the underlying disease. Extreme prematurity, the presence of intra-uterine inflammation (antenatal chorioamnionitis), and changes in alveolar development (fewer, but larger and more simplified alveoli caused by disruption alveolarization) resulting from early extrauterine lung growth further alter lung growth and development. More mature preterm and full-term infants requiring ventilator support are also potentially at risk for developing BPD and subsequently CLD of infancy. Conditions that can cause CLD of infancy include pneumonia or sepsis, meconium aspiration pneumonia, pulmonary hypoplasia, persistent pulmonary hypertension of the newborn, apnea and various congenital malformations involving the cardiorespiratory system (tracheoesophageal fistula, congenital diaphragmatic hernia, and congenital heart disease), and congenital neuromuscular disorders. (For further information, see Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn.)

Children born very preterm experience more upper and lower respiratory illnesses and more episodes of recurrent wheezing throughout childhood and adolescence. In addition to higher rates of rehospitalization in the first year of life, very preterm children with and without BPD have higher healthcare utilization throughout childhood with higher rates of continued medication usage into adolescence and adulthood. Bronchopulmonary dysplasia with or without chronic oxygen dependency after NICU discharge predicts poorer neurodevelopmental outcomes at 36 months corrected age (age adjusted for the degree of prematurity).

Respiratory function studies performed at various times throughout childhood into young adulthood in preterm children who develop BPD demonstrate persistent reductions in airflow and higher airway

resistance. The more preterm the child or young adult was at the time of birth, the greater the airflow reductions involving primarily the smaller airways and air trapping; reductions in FEV1 (forced expiratory volume in 1 sec) are largest among individuals born at less than 26 weeks' gestation. FEV1 reduction is also present in children and adults born preterm who did not develop BPD in comparison with children and adults born at term. Increased airway reactivity is also a common finding, particularly among preterm young adults born earlier than 27 weeks' gestation. Despite these changes, most extremely low-birth-weight (ELBW) and extremely preterm survivors are asymptomatic and have pulmonary function and exercise capacity similar to those of adults born full term. Recent studies have also identified that adults born preterm have abnormal paradoxical ventilatory responses when they are exposed to hypoxic or hyperoxic environments. This has implications for individuals with concomitant sleep-disordered breathing (obstructive sleep apnea) and those individuals residing at high altitude.

### Child Vulnerability and Parental Adaptation to Preterm Birth

The experience of giving birth to an infant who has a prenatal diagnosis or requires neonatal intensive care is traumatic for families. A prolonged hospitalization, the diagnosis of a chronic health condition, being the medically fragile survivor of a complicated neonatal hospital course or multiple pregnancy, and, in some instances, even a non-life-threatening, self-limited condition such as hyperbilirubinemia or transient tachypnea of the newborn can predispose the child to *vulnerable child syndrome*. Parental reactions to their child's illness or perceived vulnerability can have long-term psychological consequences, with deleterious effects for the child and family. Among the observed parental responses can be excessive concerns about the child's health and development leading to hypervigilance, medical visits for minor symptoms, separation problems, difficulty with limit setting, sleep disorders, and underestimation of the child's abilities and potential. Parental stress can also lead to family dysfunction, increase the risk for child maltreatment (either of the child who is ill or of a sibling), and affect the parents' own health and well being.

The severity of the stress experienced by parents has been shown to correlate with later depressive symptoms and posttraumatic stress disorder (PTSD) among parents of high-risk infants. The prevalence of PTSD among parents of children with chronic illness is reported to be as high as 23%. Depressive symptoms may vary over time and by parent gender. Parents experiencing more depressive symptoms or parenting stress, or who have a weaker sense of coherence (control), report more behavioral and emotional problems in their very low-birth-weight (VLBW) children. Parents' information needs and reactions are also influenced by their history, expectations, coping strategies, and experiences. Concerns about long-term developmental outcomes and the need for information do not diminish over time. Carnevale and colleagues identified 6 themes among parents caring for a child with a

chronic illness and technology dependence that inform the information, resource, and support needs of families of high-risk, medically complex infants: confronting parental responsibility, seeking normalcy, conflicting social values, living in isolation, concern over the “voice” of the child, and questioning the “moral order,” or fairness, of life.

The perception of child vulnerability and heightened vigilance among parents of very preterm children and adolescents may be an important factor in the finding of lower rates of risk-taking behaviors, including alcohol, smoking and drug use, and early sexual activity among adolescents and young adults born preterm. This observation is consistent in single-center and population-based studies in the United States, Canada, Scandinavia, and Australia. Parental mental health and family functioning have also been shown to improve (normalize) over time.

## OVERVIEW OF SHORT- AND LONG-TERM OUTCOMES

### Prematurity

Outcomes data for preterm infants have focused principally on the VLBW or extremely preterm infant. The emphasis on babies born early or with a LBW is growing because of the increased understanding of the short- and long-term morbidities experienced by these children, as well as the effect on their cognitive and developmental performance. Male preterm children are reported to have more

behavioral problems and higher disability rates than female preterm children.

### Very Low-Birth-Weight, Extremely Preterm Infants

The National Institute of Child Health and Human Development (NICHD) Center for Research for Mothers and Children Neonatal Research Network has been prospectively collecting data regarding VLBW preterm infants and children since 1993. Survival rates for infants born during the 1990s between 23 and 32 weeks' gestation have increased. Table 115-1, Table 115-2, and Table 115-3 summarize the early outcomes data for this group of infants. Rates of low mental developmental assessment scores and neurodevelopmental impairment at 18 to 22 months of age declined in infants born in the late 1990s, and the improved outcomes correlated with antenatal steroid administration to promote fetal lung maturity. Among infants born weighing less than 1,500 g (3.3 lb), reports of survival and morbidity rates through the first 4 months of life have changed little since the mid-1990s. The survival rate for infants born from 1997 to 2002 with birth weights between 501 g (1.1 lb) and 1,500 g (3.3 lb) is 85%. Birth weight-specific survival for babies born during this period weighing 501 to 750 grams (1.10–1.65 lb) is 55%. The survival rate improved to 88% for infants weighing 751 to 1,000 g. For infants with birth weights in the weight groups 1,001 to 1,250 g (2.2–2.75 lb) and 1,251 to 1,500 g, survival is similar at 94% and 96%, respectively. Among infants

Adapted from Laptook AR, O'Shea M, Shankaran S, Bhaskar B, and the NICHD Neonatal Network. Adverse neurodevelopmental outcomes among extremely low birth weight infants with a normal head ultrasound: prevalence and antecedents. *Pediatrics*. 2005;115(3):673–680.

born between 1993 and 1998, extremely preterm infants with gestational ages between 27 and 32 weeks showed a significant decline over time in the percentage with a mental developmental index (MDI) score of less than 70. In contrast, rates of cerebral palsy (CP) for all infants between 22 and 32 weeks remained stable, as did the percentage of infants with MDI scores less than 70 who were born at 22 to 26 weeks' gestation.

#### Factors Influencing Outcomes of Extremely Low-Birth-Weight Infants

Improvements in antenatal and postnatal care have contributed to a reduction in some sequelae. Survival without neonatal major morbidity (BPD, intraventricular hemorrhage [IVH], and necrotizing enterocolitis) has remained unchanged at 70%. A nearly 20% increase has been reported in the survival rate of VLBW infants born of a multiple gestation. Postnatal growth failure, common among immature and sick infants, has also decreased. Among the least mature infants weighing 501 g to 750 g, morbidity rates have increased since the mid-1990s. Only 20% of these infants are reported to be morbidity free. Babies born weighing 751 to 1,000 g fare somewhat better, with 33% exhibiting major neonatal morbidity; 55% of these infants are free of neonatal morbidities by 4 months of age. Similar differences are seen when the infants are grouped by gestational age (see Table 115-1). Neonatal nutrition and postnatal growth are additional factors that influence outcomes at 18 to 22 months of age, as summarized in Table 115-2. Adequacy of postnatal growth also influences school-aged outcomes; infants with postnatal growth problems exhibit poorer cognitive scores and academic achievement. Preterm infants who are small for gestational age (SGA) at birth but who demonstrate adequate postnatal growth do not exhibit deficits similar to those seen among appropriately grown preterm infants with poor postnatal growth. Providing human milk as part of the ELBW infant's nutritional regimen seems to have a protective effect on MDI measurements at 18 months corrected age. Every 10 mL of human milk fed was correlated

with a 0.5-point increase in the MDI score. Evidence indicates that all areas of brain growth, including the whole brain, cerebral and subcortical gray matter, and cerebral white matter, are affected. Regions of the brain that are most vulnerable are the sensorimotor cortex, premotor cortex, and mid-temporal cortex. Cerebral volume at 8 years of age is related to the child's gestational age, irrespective of evidence of chorioamnionitis at birth or the presence of ventriculomegaly or periventricular leukomalacia. High rates of learning and attention difficulties, as well as minor motor impairments, occur in children born very preterm. Experts have speculated that perinatal brain injury or postnatal nutritional deficiencies predispose these children to abnormal brain development, causing reduced caudate and hippocampal volumes. Reduced caudate volume is associated with low IQ. Memory deficits are seen among children with smaller hippocampal volume.

Among very preterm and VLBW children born after the year 2000, survival to hospital discharge has increased although morbidity and intact survival rates have remained essentially unchanged as illustrated in Table 115-4.

Figure 115-1 (Extremely PT Infant Survival to discharge without morbidity, 2003–2007, NICHD NRN) summarizes the morbidity-free survival rates among very preterm infants born in the US between 2003 and 2007.

When evaluating the outcomes for VLBW children, the 3 morbidities that seem to have the most significant effect on later outcomes are BPD, severe IVH (grade 3 to 4) or periventricular leukomalacia (PVL), and severe retinopathy of prematurity (ROP). The more severe the degree of BPD or CLD is, the greater the likelihood of CP or neurodevelopmental impairment. Infants who continue to require oxygen at 36 weeks' postmenstrual age have a 17% to 27% risk of CP and a 45% to 62% incidence of neurodevelopmental impairment. The need for prolonged ventilation greater than 90 days nearly triples the risk for CP from 28% to 80%. Each of the 3 risk factors (BPD, severe IVH or PVL, and severe ROP) independently correlates with a poor outcome;

BPD, bronchopulmonary dysplasia; IVH, intraventricular hemorrhage; PMA, postmenstrual age; PVL, periventricular leucomalacia; ROP, retinopathy of prematurity. Adapted from Stoll BJ, Hansen NI, Bell EF, et al. Neonatal outcomes of extremely preterm infants from the NICHD Neonatal Research Network. *Pediatrics*. 2010;126:443–456.

the presence of 2 or more of these risk factors significantly increases the likelihood of an adverse outcome that includes CP, cognitive delay, severe hearing impairment, and bilateral blindness.

Among ELBW infants, poor long-term outcome was present in 18% of children without BPD, brain injury, or severe ROP. In contrast, 88% of children with all 3 morbidities experienced a poor outcome. Important caveats to these findings are that not every infant who sustains a grade 3 or 4 IVH will develop CP, and, conversely, a normal neurosonogram (showing no evidence of IVH or PVL) does not always predict a good outcome. Among babies in the NICHD cohort who had normal head ultrasound examinations, 9.4% were diagnosed with CP, 25% had cognitive delay, and nearly 30% exhibited motor delays. Factors associated with neurodevelopmental impairment (CP or MDI score below 70) in babies with normal neurosonography are male gender, multiple birth, lower birth weight, pneumothorax, prolonged mechanical ventilation, maternal race and education, and poverty. (Table 115-3 summarizes the degree of risk associated with each of these factors.) Late-onset

sepsis has also been shown to negatively affect the outcome for ELBW neonates, increasing the risk for CP, low MDI, low psychomotor developmental index, and vision impairment. At 30 months' corrected age, the majority of unimpaired ELBW/extremely preterm children have cognitive scores toward the lower end of the normal distribution with mean MDI scores of 100 or less on the Bayley examination. Exposure to antenatal steroids is associated with a greater likelihood of an unimpaired outcome.

Regional and national differences have been reported in mortality and morbidity rates. European outcomes reported for infants born less than 1,000 g are notable for lower survival rates and increased rates of morbidity in comparison with outcomes for infants born in the United States during the 1990s, but demonstrate improved survival of infants born after 2005 who are 24 to 25 weeks' gestation. An important consideration when reviewing data from various countries is understanding the approach to perinatal and neonatal care delivery (including at what gestation and birth weight resuscitation is offered), the

**Figure 115-1** Extremely preterm infant survival to discharge without morbidity, 2003–2007. (Adapted from Schmidt B, Asztalus EV, Roberts RS, et al. Impact of bronchopulmonary dysplasia, brain injury, and severe retinopathy on the outcome of extremely low-birth-weight infants at 18 months: results from the trial of indomethacin prophylaxis in preterms. *JAMA*. 2003;289:1124–1129.)

scope of care available, the decision processes regarding termination of care, and whether the infants for whom outcomes are reported are population based or reflect only those infants admitted to the NICU.

### Neurodevelopmental and School-age Outcomes

Understanding the scope and evolution of neurodevelopmental outcomes requires surveillance through childhood into adulthood. Longitudinal outcomes that reflect the effect of current approaches to perinatal care take decades to elucidate. The earliest neurodevelopmental outcomes are typically reported between 18 and 22 months of age, with school-age outcomes, particularly at age 8 years, being the most predictive of future performance. Functional outcomes have recently been reported for several cohorts of preterm young adults who have been followed longitudinally in the United States, Canada, Europe, and Australia since their birth. Sequential follow-up is necessary as neurodevelopmental function has been shown to improve with time for many preterm, VLBW children. Evidence is increasing of neurodevelopmental recovery with improvement in functional outcomes and verbal and IQ testing with advancing age. Ment et al reported on full-scale, verbal, and performance IQ test scores for VLBW children with and without IVH between 3 and 8 years of age. Between 4.5 and 6 years of age, improvements in mean IQ scores were evident in both groups of VLBW children. By 8 years of age, the mean full-scale IQ score was reported to be 96 for VLBW children without a history of IVH and 94 for VLBW children with a prior IVH. Verbal IQ is

higher than performance IQ for both groups of children. Forty-five percent of the children monitored demonstrated at least a 10-point gain; 12.5% had a 5- to 9-point increase in their scores.

Behavioral and emotional outcomes have been reported by investigators in the United States, Canada, Europe, Australia, and New Zealand. The range of problems encountered include hyperactivity, conduct problems, emotional symptoms with both internalizing and externalizing behaviors, peer difficulties, attention problems, delinquent behavior, and social problems. Generally, a 1.5- to 3-fold increase is found in these problems in comparison with healthy children born at term gestation.

Developmental coordination disorders are also more common in preterm, LBW children. Developmental coordination difficulties correlated with behavior problems and poorer cognitive function and academic performance, and were more prevalent among EBLW and very preterm male children. Adaptive behavioral and externalizing problems were more often demonstrated. Of interest, preterm male children more often exhibit externalizing behaviors, whereas preterm girls demonstrate more internalizing behaviors.

Neuropsychological deficits are reported to be both global and specific in nature, with greater involvement in a range of educational areas involving attention, language, sensorimotor and visuospatial abilities, and verbal memory. An increased incidence of nonverbal learning disabilities, borderline cognitive function, and fine-motor problems has been reported; verbal cognitive skills typically exceed nonverbal abilities. Aspects of

functioning that are affected include visual-motor integration, visual perception, mathematics and spatial skills, and fine-motor speed. Beyond nonverbal learning difficulties, problems with verbal abstracting (inferences), reading comprehension, written output, and social skills are exhibited. Reading decoding has not been shown to be affected. These deficits are associated with problems in executive functioning—organization, planning, problem solving, and abstraction. Estimates of visual-perceptual and visual-motor integration problems range from 11% to 20%. Fine-motor difficulties are reported to occur in up to 70% of ELBW children. Speech and language impairments are common in children born preterm. Delays can be found in expressive language, receptive language processing, articulation, and phonological short-term memory (the capacity for holding a small amount of information in mind in an active, readily available state for a short period of time for easy retrieval). Although vocabulary and receptive language are within normal limits for LBW children, preterm children have more difficulty with more complex verbal processes such as understanding syntax, abstract verbal skills, verb production, and the length of phrases or sentences produced. Critical to academic and social success, these language difficulties are also significantly influenced by the child's environment and language experiences.

As a group, 50% to 70% of VLBW and ELBW children, respectively, require educational assistance in school. By middle childhood, ELBW children are 3 to 5 times more likely to have difficulties with reading, spelling, mathematics, or writing. Grade retention is reported for 23% to 39% of LBW children; up to one-third exhibit school problems, with particular difficulty in mathematics and reading. Fifteen percent to 28% continue to require special education. Over 50% of preterm children without any neurosensory impairment enrolled in a mainstream educational setting may require additional educational support. Common factors that influence outcomes include parent involvement, parent perspectives about and approaches to the child's limitations, maternal education and socioeconomic status, and access to services.

Longitudinal follow-up of ELBW children into late childhood and early adolescence (ages 10–14 years) continues to confirm residual effects of extreme prematurity. There is an increased trend toward depressive symptoms that is more prevalent among preterm children who have poorer family functioning, social risk factors, and the coexistence of a chronic medical condition. By 10 to 12 years of age, most (85%) extremely preterm children will be functioning in mainstream academic environments without significant adjustment problems. VLBW children with BPD experience more significant cognitive and academic impairments than VLBW children without CLD. Decreased functioning is present in the areas of cognition (intelligence), reading, mathematics, and gross-motor skills, with greater utilization of special educational services.

### **Chronic Conditions, Functional Limitations, and Special Health Care Needs**

Extremely low-birth-weight infants are affected by more chronic health conditions that contribute to

functional limitations and increase service and technology utilization. Hack et al reported that the health conditions most prevalent at 8 years of age are asthma, mild hearing impairment, visual disability, and CP. Blindness and hearing loss requiring hearing aids also occurred but were less common. These conditions correlated with school performance and academic deficiencies, including low IQ, limited academic skills, poor motor skills, and poor adaptive functioning. Farooqi et al confirmed these findings in their report on health and functional outcomes for a group of Swedish extremely immature preterm children tracked until 10 to 12 years of age.

Among preterm infants with CLD, over 50% exhibit airway reactivity. Postdischarge mortality can occur because these infants are at risk for sudden death. Lung function improves between 8 and 14 years of age, at which time rates of asthma are similar to NBW children, and lung function is within the normal range. Pulmonary function testing reveals lower airflow but no difference in lung volumes or air trapping, irrespective of whether the ELBW child had BPD.

An increased prevalence of tooth enamel defects affects both the primary and permanent teeth of preterm infants. Eruption of the first tooth in preterm girls has been reported to occur later than in preterm boys. However, by the age of 2 years, no significant delays in tooth maturation are observed between preterm and full-term children. Maturation of permanent teeth was also not noted to be delayed in the preterm children. The presence of palatal grooves and a high arched palate caused by prolonged intubation and orogastric tube placement can also affect oral health, feeding, and normal speech development.

### **Vision Function and Retinopathy of Prematurity**

Strabismus, myopia, and poor visual acuity are more common in preterm children. More than 33% of ELBW children require prescription glasses, compared with 10% of full-term children. Difficulties with visual-motor integration in middle childhood are strongly related to the presence of visual impairment. Mild ROP has not been shown to be correlated with decreased visual acuity at age 7 years. Stephenson et al reported on visual and cognitive outcomes in late childhood and early adolescence for a cohort of LBW children whose birth weights were less than 1,701 g. Among children aged 10 to 13 years with a history of ROP, 50% had an adverse ophthalmologic outcome, with myopia, strabismus, and reduction in visual acuity predominating. Additional visual abnormalities involved color vision and visual-field defects. Children between the ages of 10 and 13 years with a history of mild ROP (stages 1 and 2) did not experience adverse visual outcomes. When outcomes for children with and without treated severe ROP (threshold ROP) are evaluated, there is a 10-fold increase in the rate of functional limitations involving 4 or more of the following areas: vision, hearing, speech, ambulation, dexterity, emotion, cognition, and pain. Children with severe ROP showed a significant difference in the severity of functional limitations when sighted children are compared with blind or low-vision VLBW

children—6.4% versus 46.5%, respectively. A recent study explored the question of whether the visual problems experienced by preterm infants are the result of common associated morbidities, ROP, IVH or PVL, or premature exposure to extrauterine visual stimulation. At 5 to 7 months corrected age, preterm infants without evidence of ROP or neurologic abnormalities exhibit visual function that is not significantly different from that of healthy infants born full term.

### Growth

Preterm children are at risk for incomplete catch-up growth, largely because of postnatal growth deficiency that develops in the weeks to months after their early birth. Growth, weight gain, and nutrient accretion that parallel intrauterine accretion postnatally are not achieved by many LBW infants. Four growth patterns are seen among preterm and sick infants.

- The infant is appropriate for gestational age (AGA) at birth and continues to grow along a gestation-specific intrauterine growth curve
- The infant is AGA, but postnatal growth falls below the curve
- The infant is SGA at birth, but demonstrates catch-up growth
- The infant is born SGA and remains below the curve

Postnatal growth failure is common among preterm and LBW children born at less than 32 weeks' gestation and less than 1,500 g birth weight. The incidence of extrauterine growth restriction is common, reported at 28%, 34%, and 16% for weight, length, and head circumference, respectively. For each growth parameter, the incidence of extrauterine growth restriction increased with decreasing gestational age and birth weight and was influenced by the infant's illness severity. Poor physical growth is associated with suboptimal nutrition, poor feeding skills, prolonged hospitalization, chronic respiratory disease, and late-onset sepsis or infection. At 1 year of age, a significant percentage of these infants continue to demonstrate subnormal growth (<10%) for weight, length, and head circumference. The rate of neonatal hospital weight gain and head growth also influences growth and neurodevelopmental outcomes at 18 to 22 months of age. Poor postnatal growth, particularly head growth, has been correlated with residual suboptimal growth and neurodevelopmental impairment at 7 years of age.

Larger, more stable infants typically demonstrate catch-up growth during the first and second years of life. VLBW and ELBW children may not exhibit catch-up growth by the third year and, as a group, tend to remain permanently lighter and shorter than children born at full term. Doyle et al reported that weight measurements among VLBW children were 1 standard deviation below the mean for age at 2, 5, and 8 years of age, with catch-up achieved by 14 years of age. At 8 to 12 years of age, preterm children also have lower fat mass and body mass index than full-term children. Similar results have been reported by Farooqi et al on children born extremely preterm at 23 to 25 weeks' gestation. At 11 years of age, these ELBW children were significantly smaller on all growth parameters than their full-term counterparts, despite evidence of

catch-up growth beginning by 3 months' postnatal age. Of additional importance was the finding that among this group of children, catch-up head growth did not occur after 6 months of age.

### Cardiovascular Health

Preterm birth and very low birth weight are associated with an increased risk for later cardiovascular disease (CVD) that appears to be related to structural changes in the developing cardiovascular system that occur because of the early birth. Infants born preterm have systolic blood pressures that average 3 to 4 mm Hg (range 2.5–6) above the mean for their age. This elevation in systolic blood pressure is evident from mid- to late childhood and persists into adolescence and adulthood. Women born preterm appear to be at greater risk than preterm men. However, recent meta-analyses have not confirmed an association with a higher rate of metabolic disease among adults born preterm, although preterm adults do appear to have higher levels of plasma low-density lipoprotein, a risk factor for atherosclerosis and cardiovascular disease. Although children born preterm are reported to weigh slightly less and be slightly shorter than children born at term during childhood and adolescence, there are several reports of increased abdominal adiposity and higher BMI with more truncal fat among men who were born preterm. Affected individuals are also more likely to have abnormal lipid profiles. At present we do not have a full understanding of the mechanisms that predispose preterm adolescents and adults to this greater cardiovascular risk, but there is evidence that preterm and very low-birth-weight individuals have higher pulse pressures and alterations in carotid intimal thickness (a marker for atherosclerosis), contributing factors to CVD. Cardiac magnetic resonance imaging studies have determined that preterm individuals have increased left ventricular mass in adult life with evidence of functional and structural changes. These findings may be the manifestation of the effect of the need for the preterm infant to adapt to an extrauterine environment at a developmental stage in cardiac development that disrupts or disorders the normal developmental processes leading to the changes described and to the resultant increased cardiovascular risk.

### Pain Sensitivity

Long-term consequences occur as a result of repetitive painful and noxious stimuli during the neonatal period. Preterm children have lower-than-normal response thresholds to tactile stimulation and seem hypersensitive to pain. At 4 to 5 years of age, significantly increased somatization occurs. Repetitive pain leads to an altered pain system with decreased pain thresholds. At 8 to 10 years of age, ELBW children have similar perceptions of pain intensity, although they rate medical pain more intensely than psychological pain and ascribe higher intensity ratings to recreational pain. More preterm children report fatigue (13%) and anxiety (8%) than children who were born at term. Preterm adolescent girls exhibit greater pain sensitivity than preterm adolescent boys.

### Adolescence and Young Adulthood

Longitudinal outcomes data are being reported throughout the United States, Canada, Australia/New

Zealand, and Europe for groups of preterm children who are now adolescents and young adults. Assessing outcomes during adolescence has yielded interesting data about parental and adolescent perceptions regarding the preterm teenager's health, well being, and functional abilities. In recent years, numerous publications have reported on the adolescent and young adult outcomes for preterm and LBW children born during the late 1970s and early 1980s. Most of the reports detail outcomes for very preterm infants less than 32 weeks' gestation and VLBW infants. In the last decade, particular attention has been paid to the consequences of extreme prematurity and extremely low birth weight. Although concerns have been raised regarding the applicability of these outcomes to preterm and LBW children born today, comparison shows that

outcomes for children born in the late 1990s and early 2000s are similar to those reported for the older cohorts of preterm or LBW individuals. Continued reporting of the longitudinal consequence of early birth will further enhance physicians' ability to counsel families and develop appropriate surveillance programs for children born preterm. Overall, the transition to young adulthood is fairly comparable to young adults who were born with NBW and at full term. Three areas of difference are persistence of neurodevelopmental disability, lower educational achievement, and suboptimal growth despite catch-up growth. Table 115-5 and Box 115-1 summarize the data on young adult outcomes.

Longitudinal follow-up of growth among a group of VLBW infants at 2, 5, 8, and 14 years has been

**Table 115-5** Transition to Adulthood

OUTCOME	EXTREMELY LOW-BIRTH-WEIGHT GROUP (%)	COMPARISON NORMAL-BIRTH-WEIGHT GROUP (%)
Completed university education	5	14
Pursuing postsecondary education	32	33
Completed less than high school	15	11
Permanent employment	48	57
Unemployed <sup>a</sup>	26	15
Married or cohabiting	23	25
Living with parents	11	14
Visual problems <sup>b</sup>	64	37
Neurosensory impairment <sup>b</sup>	27	2

### BOX 115-1 Adult Outcomes for Preterm and Low-Birth-Weight Infants

#### INTELLIGENCE AND ACADEMIC ACHIEVEMENT

- Mean IQ: 81–98
- IQ <85: 19%–49%
- Completed high school or obtained a general education degree: 56%–85%
- Post-high school: 37%–38%

#### WORK STATUS

- Full-time employment: 48%
- Unemployed, not in school: 14%–26%

#### HEALTH STATUS

- Chronic illness or disability: 47%
- General health
  - Similar to term adults
  - Increased frequency of reactive airway disease or asthma
- Growth
  - Weight: below normal in infancy followed by catch-up growth

- Height: shorter relative to peers and mid-parental expected height
- Body mass index: normal as teen and young adult
- Head circumference: remains below normal
- Neurosensory
  - Impairment (cerebral palsy, blindness, deafness): 12%–28%
  - Vision problems: 37%
  - Retinal detachment: 4%–7%

#### SOCIAL BEHAVIOR

- Significantly less risk-taking behavior
  - Drug and alcohol use
  - Sexual activity
- Similar rates of conviction and incarceration
- Similar rates of independent living, marriage, cohabitation, and parenting

reported for a cohort of Australian youth born between 1977 and 1982. Pubertal development in these individuals was similar to that seen for full-term controls. These VLBW teenagers were significantly shorter and lighter, with smaller occipitofrontal head circumference measurements than their NBW counterparts. Children with birth weights less than 1,000 g had lower weight scores during childhood but not at 14 years when compared to children born weighing 1,000 to 1,499 g. Among this latter group, lower height scores were present only at 2 years of age. However, significantly lower head circumference measurements were noted on the serial assessments. Hellgren et al reported on a group of preterm Swedish youth at 15 years of age. Significant differences were found in visual acuity, stereo acuity, and astigmatism, as well as full-scale (85 vs 97) and performance (87 vs 99) IQ.

Preterm adolescents who had evidence of brain injury performed more poorly on all achievement tests than term adolescents. Nearly 50% of teens with brain injury had associated visual dysfunction, and 33% had learning disabilities. Visual dysfunction is related to white matter injury in preterm infants causing subnormal visual acuity complicated by perceptual and cognitive visual problems. Rogers et al found significant differences in motor performance in unimpaired ELBW preterm adolescents at 17 years of age, with decreased aerobic capacity, strength, endurance, flexibility, and activity level. The teens reported a more inactive lifestyle with less previous or current sports participation, poorer coordination, and more difficulty maintaining rhythm and cadence.

Parents report a high incidence of mental health problems in VLBW teens. They describe more social and attention problems and less social and school competence among VLBW boys than is seen among term adolescents. Parents also reported more internalizing behaviors (withdrawn, somatic complaints, anxious or depressed) and social and attention problems and less school competence in VLBW girls than is seen among term adolescents. Interestingly, teenage VLBW boys report that they are more active and have less psychological distress and fewer problems with attention than teens who were born full term. Teenage VLBW girls also describe externalizing behaviors, being less social with fewer thought and attention problems, and higher activity levels. Discrepancies exist between parent-reported problems and competencies and teen self-reports. Notably, teens who were SGA or girls self-reported more total problems and internalizing behaviors than NBW teens and boys. These results have been seen across several studies in the United States, Canada, and Europe. At 15 and 16 years of age, preterm teens do not rate their health status and HRQL differently than comparison group teens born at term, with the exception of reporting a higher level of cognitive difficulty (40.7% vs 25%). Teens who were born preterm exhibited wider variation in their functional abilities. Saigal and colleagues found that preterm teens described similar self-worth as full-term teens on most domains of self-esteem, although some gender effects regarding athletic competence and physical appearance were noted. Boys rated themselves more highly than girls. Among another

cohort of Canadian ELBW adolescents born between 1981 and 1986, lower than normal cognitive scores and academic skills were reported. ELBW teens reported lower than expected scholastic, athletic, job, and romantic competence. These teenagers viewed themselves as more likely to need help getting a job.

Evaluation at 12 to 16 years of age among a longitudinal cohort born in Ontario found that more of the ELBW teenagers had neurosensory impairments—28% versus 2% of term teenagers. These ELBW adolescents exhibited a higher incidence of visual problems (57% vs 21%), seizures (7% vs 1%), developmental delay (26% vs 1%), learning disabilities (34% vs 10%), and hyperactivity (9% vs 2%), as well as more use of specialists and community resources, than adolescents born at term. Teenagers who were born weighing less than 750 g were the most disadvantaged, with 58% requiring special educational assistance or grade retention (or both), as compared to 13% of the full-term controls, a 4.5-fold greater risk for the ELBW group. A difference of 13 to 18 points was found on psychometric testing. Developmental measures at 8 years of age have been shown in numerous studies to predict reduced academic performance.

Most very preterm and VLBW adolescents are educated in mainstream classroom settings, although a percentage of these students continue to require additional educational supports, and approximately 5% to 10% have severe motor or neurosensory impairments. Parents of these extremely preterm teens attending mainstream classes report an increased incidence of problems with physical health and family functioning, and the students' teachers rated these teens as slower than normal. Only 29% of the extremely preterm adolescents attending mainstream classes were without health issues compared to 49% of their term classmates; 100% of the extremely preterm teenagers in special education classes had health problems. Asthma, vision problems, learning disabilities, and behavioral problems were the most commonly reported. The psychological effect on parents of these teens' health issues was greatest for those whose children were in special education. Extreme prematurity affected both family functioning and family life. Teens' self-assessment of their own health did not differ from controls. In addition, no apparent difference was found in the onset of puberty in girls or boys. Similar rates of medication and tobacco use, but decreased alcohol and recreational drug use, were reported for mainstream and special education preterm students. Increased health service use was reported only among the special education preterm teens. When future plans were queried, a lower than normal proportion of the extremely preterm teens were planning to continue in school or attend vocational training, with additional planning for low-skilled types of employment.

### The Role of Early Intervention

Few data are available about the specific benefits of early intervention for very preterm and VLBW children. The Infant Health and Development Program is the only randomized clinical trial to evaluate the longitudinal effects of an intensive 36-month

early-intervention program for LBW infants and their parents. The study population was composed of 985 LBW preterm infants (a *light low-birth-weight* [LLBW] group at or below 2,000 g and a *heavy low-birth-weight* [HLBW] group weighing 2,001 to 2,500 g). Infants in these groups were randomized to receive routine follow-up care or to participate in an intensive home- and center-based group intervention that lasted 3 years. Major assessment points were at 3, 5, and 8 years of age. At 36 months corrected age, children in the intervention group had higher scores than children in the follow-up-only group on tests of receptive language, cognitive development, and visual-motor and spatial skills. The effects were the strongest for families with the greatest risk (ie, children whose parents had a high school education or less and who were of ethnic minority status). The intervention was found to be effective for the HLBW infants but not for the LLBW infants. McCarton et al found no overall significant differences between the intervention and follow-up groups. However, a subsample of the HLBW children who participated in the intervention group had higher scores on several cognitive tests (receptive vocabulary, mathematics, overall IQ) than the subsample of HLBW children in the follow-up group. The difference between the 2 groups at later ages was less than that seen at age 3; thus, the effects of the intervention program seemed to decline over time. Among the LLBW children in the intervention group, all of the earlier positive effects had disappeared by age 8. Reassessment of these individuals at age 18 revealed a continued 4-point achievement advantage for the HLBW group that remained stable over time. Intervention participants also exhibited fewer risky behaviors. Similar to the results seen at age 8, loss of intervention benefits was demonstrated in the LLBW group. The high school drop-out rate was lower than that reported for other groups of potentially high-risk students.

### Young Adulthood

Examination of young adult outcomes reveals findings similar to those from adolescent age-reported outcomes. In general, the findings related to growth, academic and employment achievement, personal satisfaction, and HRQL are comparable to the results seen during adolescence. In a report assessing 20-year-olds born with VLBW, fewer than expected graduated from high school (74% vs 83%). Furthermore, VLBW men are significantly less likely than expected to be enrolled in postsecondary education (30% vs 53%). Testing reveals lower than normal mean IQ scores (87 vs 92), lower than normal academic achievement scores, higher than normal rates of neurosensory impairments (10% vs 1%), and subnormal height (10% vs 5%). Less than expected alcohol and drug use was noted, with lower than expected rates of pregnancy in the young adults both with and without neurosensory impairment. When growth was evaluated, VLBW young women in this group were reported to catch up by 20 years of age, whereas VLBW young men remained significantly shorter and lighter than NBW young men. Predictors of growth attainment at 20 years included maternal education and height,

race, birth-weight z score, length of NICU stay, and chronic illness at 20 years of age. In contrast, another study reports that among VLBW adults (20 years), weight and height were not different from the general population and were consistent with parental height. Among this group of young adults, the mean body mass index was 24.0, and findings revealed that the VLBW adults were relatively heavy for their height.

Similar findings have been reported in Canada and Sweden. Assessment of the Ontario preterm young adults at 22 to 25 years revealed that 27% had residual neurosensory impairments yet had similar rates of graduation (82% vs 87%) and no significant differences in educational attainment (32% vs 33% postsecondary education), employment (48% vs 57%), independent living, marriage or cohabitation, or living with parents than the NBW controls. Lindstrom found that among 23- to 29-year-old preterm adults, 13.2% of individuals born between 24 and 28 weeks' gestation and 5.6% of individuals born between 29 and 32 weeks' gestation received economic aid because of handicap or chronic illness. Adults who were born between 33 and 37 weeks' gestation also exhibited significant risks for disability, accounting for 74% of the total disability associated with preterm birth in this population-based study. Preterm adults were also less likely than expected to complete postsecondary education and had a lower than average net income. These findings were further supported by a report from Lefebvre et al, who demonstrated that most preterm adults had a mean adult IQ that was in the normal range but more than 1 standard deviation below that of NBW controls. Again, school failure, IQ less than 85, and use of special educational assistance were more prevalent than normal among the preterm group.

Measurement of quality of life and social activities in preterm young adults continues to demonstrate less alcohol and illicit substance use than full-term controls, although the frequency of smoking and sexual activity was similar between groups. In the United Kingdom cohort on which Cooke reported, preterm young adults had more children; were shorter, less satisfied with their appearance, and more likely to use regular prescription medication; and had less higher education than their term counterparts. Employment rates were similar to the adults born at term. Hack et al, reporting on the Cleveland cohort of VLBW adults, determined that VLBW men exhibited fewer delinquent behaviors but showed no differences in internalizing, externalizing, or total behavior problems than NBW men. Parents continued to report significantly more than expected thought problems for their sons. VLBW women were more withdrawn and exhibited more internalizing behaviors (anxious or depressed) and fewer delinquent behaviors than NBW men; their parents reported significantly more than expected anxiety and depressive symptoms and attention problems. No differences in self-report of attention-deficit/hyperactivity disorder were noted. Allin et al assessed personality among adults who had been born before 33 weeks' gestation and found different personality characteristics in the very preterm group, with lower than expected scores on extraversion and higher than normal levels of neuroticism

among female participants. These results are similar to those reported by Hack: decreased risk-taking and antisocial behaviors, primarily among female participants, who reported less than expected recreational drug use and sexual activity. Saigal confirms these findings, noting that among the Ontario cohort, 27% of the ELBW adults tracked had residual neurosensory impairments (13-fold higher than NBW adults) and were more likely to have multiple impairments. No overall or gender difference was noted in current health status for physical or mental health and emotional state scores between the ELBW and NBW adults. However, VLBW adults did report increased rates of seizures (8% vs 2%; odds ratio 3.8), asthma in men (18% vs 3%; odds ratio 6.3), and recurrent bronchitis (6% vs 1%; odds ratio 8.5), and a higher than expected prevalence of chronic health conditions and functional limitations in the previous 6 months. Areas of functional impairment were broad, encompassing vision, hearing, dexterity, clumsiness, and learning disabilities. Higher than normal rates for use of antidepressant medications, prescription glasses, and home care services were noted. VLBW adults also demonstrated weaker handgrip strength and lower scores in physical self-efficacy, perceived physical ability, and physical self-confidence than NBW adults. An important yet unexpected finding was a 4% incidence of late retinal detachment, with an additional 6.6% of study participants found to have retinal tears. The 15-year outcome Cryotherapy for Retinopathy of Prematurity Cooperative Group trial for threshold ROP found late retinal detachment in 4.5% of treated eyes and 7.7% of untreated eyes.

### Chapter 116

## HEALTH AND DEVELOPMENTAL OUTCOMES OF SELECTED MEDICALLY COMPLEX NEONATES

Sarah Chambers, MD; Deborah E. Campbell, MD

Advances in neonatal and pediatric intensive care have contributed to increased survival among infants whose birth is complicated by prematurity, low birth weight, congenital disorders and birth defects, and maternal conditions affecting the newborn. Among all neonates, approximately 14% require specialized newborn care in a special or intensive care nursery. Fifty-one percent of infants requiring specialized neonatal care are born at term or postterm. The infant mortality rate has steadily declined over the past several decades. In recent years, the decline has continued but at a slower rate: from 6.61 infant deaths per 1,000 live births in 2008 to 6.39 infant deaths per 1,000 live births in 2010. Congenital malformations, deformations, and chromosomal abnormalities are the leading causes of infant deaths (20.8%). Congenital diseases of the heart are among the most common congenital malformations in infants and are commonly associated with chromosomal disorders. Congenital malformations, chromosomal disorders, and congenital heart disease become less significant causes of death in children and adolescents, contributing to 2.2% of deaths in children ages 1 to 9 years in 2009. The other top conditions that contribute to infant mortality are disorders related to short gestation and low birth weight, sudden infant death syndrome, maternal complications of pregnancy, and accidental injuries.

Approximately 22% of children have a chronic health condition that affects their well-being and causes functional limitations in their day-to-day activities. Nearly 9% of children have 2 or more chronic conditions affecting their health and abilities. The prevalence of children with special health care needs increased 18% between 2001 and 2010. The infants with the greatest continuing care needs are full-term and late preterm infants with acute illness, babies with congenital malformations (eg, neural tube defects; ear-nose-throat, cardiac, gastrointestinal, or genitourinary anomalies; and genetic syndromes), and premature infants who are physically healthy but immature and have long-term health and developmental problems caused by their preterm birth.

This chapter focuses on health and developmental outcomes for the growing population of infants and children, cared for by general pediatricians and family physicians, who are born with major congenital malformations of the heart, tracheobronchial tree, and diaphragm, and infants who require extracorporeal membrane oxygenation (ECMO) treatment for neonatal respiratory failure or therapeutic hypothermia (whole-body or brain cooling) to reduce the risk for brain injury caused by hypoxic-ischemic encephalopathy. Chapter 115, Health and Developmental Outcomes of Very Preterm and Very Low-Birth-Weight Infants, provides detailed information on the health and developmental outcomes for the low-birth-weight and preterm infant and child.

### PEDIATRIC PRIMARY CARE FOR THE INFANT WITH COMPLEX MEDICAL NEEDS

Central to the ongoing health and developmental care for infants and children with complex medical needs is the medical home. A medical home is an approach to providing comprehensive primary care. (For more information, see Chapter 6, Medical Home Collaborative Care, and [www.medicalhomeportal.org/medical-home](http://www.medicalhomeportal.org/medical-home).) In a medical home, a primary care physician (PCP) works in partnership with the family and patient to assure that the medical and nonmedical needs of the child are met. Through this partnership, the PCP can help the family and patient access and coordinate specialty care, educational services, out-of-home care, family support, and other public and private community services that are important to the overall health of the child and family. A medical home provides care that is “accessible, continuous, comprehensive, family centered, coordinated, compassionate, and culturally effective.” Within some medical communities and health systems, complex medical care programs are developing that serve the function of the medical home, providing the child and the family with an interdisciplinary team of professionals who provide, coordinate, and oversee the child’s health and developmental care needs in an integrated fashion. Transitions in care across the child’s life span and into adulthood require alignment of key components of the child’s health care with the adult health care system, which should be grounded in the Institute of Medicine principles of the patient-centered medical home. The

4 principles that support a seamless transition in care over the health care continuum are

- **Family-centered partnership:** trusting, collaborative, working partnership with families, respecting their diversity and recognizing that they are the constant in a child’s life
- **Community-based system:** family-centered, coordinated collaborations designed to promote the healthy development and well-being of children and their families
- **Transitions:** provision of high-quality, developmentally appropriate health care services that continue uninterrupted as the individual moves along and within systems of services and from adolescence to adulthood
- **Value:** a high-performance health care system that has appropriate financing to support and sustain medical homes that promote system-wide quality care with optimal health outcomes, family satisfaction, and cost efficiency

### IMPACT ON FAMILIES AND FAMILY FUNCTIONING

The birth of a critically ill infant, whether anticipated because of a prior prenatal diagnosis or unexpected in the event of an urgent delivery or the onset of neonatal illness after birth, causes significant emotional distress for families. Under these circumstances diagnosis and treatment often need to be completed quickly, limiting the time for detailed discussions with anxious parents and family. In most instances, the medical indication for treatment defines the moral obligation for treatment. Ethical problems may arise when treatment is only partially successful, long-term complications occur, and questions arise related to quality of life and the relative benefits and burdens of continued treatment. Physicians and families may struggle with decisions regarding withdrawing or withholding treatment. Tensions exist as well in regard to “trial of therapy” approaches to care, with parental fears of overtreatment or of being asked to end treatment if the infant does not respond. Physicians caring for the infant may fear potential litigation if they do not offer every available therapy. Shared decision making is optimal but complex because it requires a willingness to participate, yet individual parent and family goals for their infant may change over time, as may the parents’ level of involvement. Chapter 67, Palliative Care and Bereavement, and Chapter 117, Support for Families Whose Infant Is Sick or Dying, provide in-depth discussion about shared decision making, palliative care, and family bereavement through the continuum of a child’s illness and ongoing complex health care needs.

#### Decision Making

Shared decision making is a process with decisional responsibility based on parental preferences. This requires fully informing parents and providing them complete information about the risks and benefits of treatment as well as of forgoing treatment so that they may make informed, reasoned decisions. Shared decision making requires a reciprocal exchange of information. Physicians should communicate medical information objectively to

the parents; in return, parents should share information about their values and goals for their child and family. In shared decision making, the physician's role includes active participation, sharing in the decisional responsibility, and providing evidence-based recommendations that provide a basis for parental discussions and decisions. Parents exhibit varied decision-making preferences. Respecting a family's right to determine their level of participation in decision making is both legal and ethical. It has been suggested that for parents who choose a less active role in their child's medical decision making, an appropriate compromise is a combined approach that integrates consent to give physicians decisional discretion and assent for some of the actual medical decisions.

### Palliative Care Across the Continuum of Care

*Palliative care* (Box 116-1) is an approach that improves the quality of life of patients and families facing the problems associated with life-threatening illness, preventing and relieving suffering by means of early identification, assessment, and treatment of pain and other symptoms (physical, psychosocial, and spiritual). *Supportive care* is a component of palliative care that is applicable during the course of illness, in conjunction with other therapies that are intended to prolong life, for example, ECMO, peritoneal dialysis, repair of congenital heart disease (CHD), and other interventions. Supportive care includes investigations needed to better understand and manage distressing clinical complications. *End-of-life care* focuses on the specific preparations for an anticipated death and managing the end stage of a fatal medical condition. Nearly one-third of all child deaths between birth and 18 years of age occur in the neonatal period. Twenty-eight percent of childhood deaths occur because of prematurity and low birth weight, complications of pregnancy, abnormal placentation, CHD, respiratory distress, and congenital anomalies. Thus neonatal intensive care units (NICUs) bear most of the responsibility for care of these patients.

Care for the dying or severely ill neonate should include pain and symptom management, as well as psychosocial and spiritual support for the family.

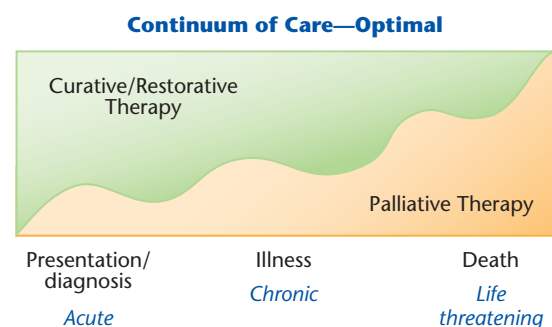

#### BOX 116-1 Palliative Care

- Provides relief from pain and other distressing symptoms
- Affirms life and regards dying as a normal process
- Intends neither to hasten nor postpone death
- Integrates the psychological and spiritual aspects of patient care
- Offers a support system to help patients live as actively as possible until death
- Offers a support system to help the family cope during the patient's illness and in bereavement
- Uses a team approach to address the needs of patients and their families, including bereavement counseling if indicated
- Will enhance quality of life and may also positively influence the course of illness

Attention to the quality of life and best interests of the child should be addressed as determined through culturally sensitive, family-centered, collaborative care decisions. Involved health care providers also require support because of the emotionally, physically, and intellectually challenging environment in which care is provided for neonates who remain unimproved despite maximal therapy. Instituting a palliative care protocol facilitates earlier identification of infants who may benefit from a more comprehensive plan of care, especially as it becomes evident that curative therapies have remained ineffective or are minimally effective. Transitioning from a curative-only to a palliative-supportive, end-of-life model of care encompasses family and staff impressions and assessments as well as communication and shared decision making. Additionally, palliative care principles can also be integrated into the care plan for all medically complex, high-risk neonates undergoing intensive care as well as the at-risk neonate in the delivery room, whether the focus is continuation of life-sustaining therapies or palliation and comfort until death occurs (see Figure 116-1).

### INFANTS WITH SIGNIFICANT CONGENITAL HEART DISEASE

Congenital heart disease is the most common severe congenital abnormality in the pediatric population. The incidence of CHD varies widely, depending on the definition and the methods reported. Table 116-1 provides a summary of the incidence of CHD. Estimates of the incidence of all CHD (including trivial, clinically irrelevant lesions such as tiny ventricular or atrial septal defects) are as high as 50 to 75 per 1,000 live births. However, the incidence of moderate to severe CHD is about 6 to 8 per 1,000 live births. This includes structural defects that require expert cardiac care and medical or surgical intervention, ranging from hypoplastic left heart syndrome and total anomalous pulmonary venous return to d-transposition of the great arteries (d-TGA) and tetralogy of Fallot, to a large ventricular septal defect or a large patent ductus arteriosus. Bicuspid aortic valve incidence, not included in this number, has a relatively high incidence of 10 to 20 per 1,000 live births and is clinically significant

**Figure 116-1** Palliative care and treatment of underlying disease are integrated throughout the course of a child's illness. (From Korones D. *Pediatric palliative care*. *Pediatr Rev*. 2007;28:e46–e56.)

because of the risk for developing valvular stenosis or incompetence over time. The diagnosis of moderate to severe CHD is often made prenatally, and a delivery and perinatal care plan can be made in advance by a multidisciplinary team including the obstetrician, pediatric cardiologist, neonatologist, cardiothoracic surgeon, and the family.

Medical therapies, catheter-based interventions, and surgical techniques for the treatment of congenital heart disease have advanced significantly in the past 60 years. In the current era, most structural cardiac abnormalities can be repaired or palliated. As a result, the number of adults with CHD has surpassed the number of children with CHD. At least 85% of patients who undergo surgical treatment of CHD now reach adulthood, and most deaths resulting from CHD occur after 20 years of age. This number includes not only patients with the most common forms of CHD affecting adults (eg, congenital valve defects, atrial and ventricular septal defects, and patent foramen ovale) but also many patients with severe complex CHD. These patients, who are now surviving into adulthood, are encountering long-term complications of open heart surgery (eg, arrhythmia or conduit obstruction after tetralogy of Fallot repair), single-ventricle palliation (Fontan procedure), or orthotopic heart transplantation.

The study of the long-term outcomes in patients with CHD has become a focus of attention and research in pediatric cardiology and has contributed to the emergence of a new subspecialty in adult CHD. Medical and surgical outcomes, such as arrhythmia, ventricular failure, and the need for reoperation, have been studied, but neurodevelopmental and social outcomes have also become a focus of attention as these patients have survived to become adult members of society.

### Prenatal Diagnosis and Outcome of Congenital Heart Disease

The prenatal diagnosis of CHD is improving but still a challenge. The reported detection rates for prenatal CHD vary widely, from 23% to 57% in published studies. Two of the more recent studies report rates at the

higher end of this range, from 47% to 57%. Furthermore, there is significant variability in the detection rates of individual cardiac lesions in different studies. Table 116-2 summarizes the reported detection rates from different population studies for overall detection of CHD and detection of individual cardiac lesions. Two studies from France and the Czech Republic have analyzed the change in detection rates over time and demonstrated that for most lesions, prenatal detection rates are significantly higher in the new millennium.

There is some debate within the pediatric cardiology community regarding whether prenatal diagnosis of CHD affects the outcome of live-born infants. It is widely acknowledged that fetal diagnosis of complex CHD allows for prenatal counseling and genetic testing if indicated and can include the option of pregnancy termination. However, if the pregnancy is continued, there is debate regarding whether a prenatal diagnosis contributes to improved outcomes. Theoretically, prenatal diagnosis allows for delivery at a tertiary care center and early initiation of treatment if indicated. However, many studies have reported conflicting data regarding the benefits (and adverse effects) of prenatal diagnosis. The outcomes studied have included short-term or long-term survival, surgical morbidity and mortality, and neurodevelopmental and quality-of-life outcomes. Much of the confusion results from the small number of patients in this population and the wide variation in disease severity between (and even among) cardiac lesions. Some studies have reported that patients with a prenatal diagnosis of moderate to severe CHD (eg, d-TGA) have a decreased risk for early mortality, but others have shown no difference in neonatal mortality, especially in patients requiring univentricular palliation, such as those with hypoplastic left heart syndrome (HLHS) or pulmonary atresia with intact ventricular septum. Although there is much debate regarding the effect of prenatal diagnosis of CHD on mortality, many studies have demonstrated an improvement in neonatal morbidity when CHD is diagnosed prenatally. These improvements include reduced early neurologic morbidity in HLHS, decreased use of preoperative mechanical ventilation, administration of antibiotics, cardiac catheterization, and emergency surgery, fewer cases of preoperative cardiac failure and closure of the ductus arteriosus, and a shorter duration of postoperative mechanical ventilation. Long-term follow-up has demonstrated less residual cardiac dysfunction and a longer freedom from catheter-based reintervention or repeat surgical intervention.

The effect of prenatal cardiac evaluation and diagnosis on the mother and on mother-infant bonding patterns has also been studied. Women referred for a fetal echocardiogram have been shown to have higher anxiety levels, especially when referred for an abnormal finding on obstetric ultrasound (vs a reason such as maternal diabetes mellitus). However, these women also self-reported that fetal and pregnancy testing was reassuring. Studies of parents whose fetus is diagnosed with serious CHD show that the parents experience a crisis period similar to the process of bereavement, in which they go through the stages of shock, denial, anger, depression, acceptance, and adjustment. A study

**Table 116-1** Incidence of Congenital Heart Disease Per 1,000 Live Births

ALL CONGENITAL HEART DISEASE	9.6
All cyanotic congenital heart disease	1.4
Ventricular septal defect	3.6
Atrial septal defect	0.9
Patent ductus arteriosus	0.8

by Menahem and Grimwade has suggested that the prenatal diagnosis of serious CHD, coupled with effective prenatal counseling, may improve postnatal mother-child bonding in families that decide to continue the pregnancy. The authors postulate this may be a result of the mother having already experienced the grieving process for the loss of her previously anticipated healthy baby. There are fewer data on the effect of prenatal diagnosis of CHD on the father of the fetus. A postnatal study of father-infant attachment in infants requiring cardiac surgery before 3 months of age demonstrated normal mean scores on the Paternal Postnatal Attachment test but lower scores on the pleasure/interaction and affection/pride subscales of the test. Self-reports of the relationship by the fathers in this study vary, with some fathers reporting feeling closer to their infant and others reporting apprehension and reservation about getting too close to their infant. This is a field that merits further study in the prenatal setting. In summary, in addition to reducing the mortality and physiologic morbidity of congenital heart disease, prenatal diagnosis may improve the psychosocial environment for some patients.

### Perinatal and Surgical Outcomes

The overall survival rate of heart surgery for CHD is greater than 90% in most studies in the current era, and more than 95% in some reports. However, there are known groups of patients who are at higher risk for perinatal and perisurgical morbidity and mortality. For

example, although the outcomes after single-ventricle (Fontan) palliation have improved dramatically during the past 3 decades, the long-term survival remains between 80% and 90%. Patients with HLHS are at even higher risk; contemporary 5-year survival rates (including Fontan palliation) are 50% to 60% with expectations that 70% of infants born with HLHS will reach adulthood.

Perioperative factors have been identified that are significantly associated with outcomes following neonatal congenital heart surgery. For example, intraoperative and postoperative hyperglycemia has been associated with increased morbidity and mortality after pediatric cardiac surgery. A prospective, randomized study from Europe suggests that tight glycemic control in the intraoperative and postoperative period has a protective effect on the myocardium and reduces the body's inflammatory response and the need for vasoactive support. In the postoperative period, the amount of cardiovascular support required during the first 48 hours (measured by a vasoactive-inotrope score) is a good predictor of mortality and morbidity in young infants after cardiac surgery. Important predictors include duration of mechanical ventilation, time to negative fluid balance (diuresis), and length of stay in the intensive care unit. These perioperative factors have led to the development of prediction measures, such as the Aristotle Comprehensive Complexity Score or the Risk Adjustment for Congenital Heart Surgery (RACHS-1), that attempt to predict the risk for mortality and morbidity after congenital heart surgery.

Recent studies have reported an increased risk for neonatal death or other adverse outcomes for healthy infants without birth defects who were born at 37 to 38 weeks' (37%–38% weeks) gestation compared with those born at 40 weeks. In many centers, infants with complex CHD are electively delivered (often by induction of labor) between 37 and 40 weeks' gestational age, at a time when organ development is thought to be complete because this allows for a coordinated mobilization of expert teams in the delivery of care to a potentially critically ill neonate. However, a large study of patients with critical CHD demonstrated that babies born before 39 weeks' gestation have increased mortality compared with those born at 39 to 40 weeks. These infants also experience increased morbidities and resource use, including more days of mechanical ventilation and more days in intensive care. Interestingly, infants born after 40 weeks also experience increased mortality rates, suggesting that the ideal gestational age of delivery for patients with critical CHD may be 39 to 40 weeks' gestation.

#### **Role of Low Birth Weight and Preterm Birth**

It is well documented that infants with CHD are at higher risk for low birth weight (<2,500 g) than the normal population. Although these infants are not at increased risk for premature birth compared with the normal, non-CHD population, both low birth weight and prematurity are widely recognized as risk factors for morbidity and mortality associated with cardiac surgery. Neonates with a birth weight of less than 2,500 g have higher mortality and morbidity for cardiac surgery. Studies report 15% to 24% overall surgical mortality in critically ill low-birth-weight neonates and up to 28% mortality in infants undergoing a palliative surgery as opposed to a full repair. This raises the suggestion that primary repair may confer a survival benefit over palliation in this population. Common postsurgical morbidities include pulmonary complications (pneumonia, lobar atelectasis, pneumothorax), pulmonary hypertensive crisis, arrhythmia, renal insufficiency, seizure, and sepsis.

#### **Role of Associated Genetic Disorders and Extracardiac Malformations**

Another group known to have poorer outcomes after cardiac surgery includes those infants with associated genetic disorders or extracardiac malformations. There are known associations between certain genetic disorders and cardiac lesions, such as atrioventricular canal defects in trisomy 21, conotruncal defects (eg, transposition of the great vessels), and 22q11 deletion syndromes. Patients with genetic disorders and cardiac disease are thought to have increased morbidity and mortality associated with cardiac surgery compared to patients with a normal genetic complement. However, it must be remembered that corrective or palliative cardiac surgery in patients with genetic disorders such as trisomy 21 can also improve their long-term survival.

#### **General Long-term Health Outcomes**

As surgical techniques and postnatal care have improved, most patients with CHD now survive into

#### **BOX 116-2 Nutrition Goals**

- Weight gain goals are 20 to 30 g/day during the first 3 months of life; 18 to 20 g/day from 3 to 6 months of age.
- Infants and children with CHD have caloric needs 120% to 140% higher than the recommended daily allowance.
- Infant caloric requirements can be 130 to 170 kcal/kg/day to achieve adequate weight gain.

#### **BOX 116-3 Strategies for Nutritional Support**

- Consider the route of feeding: supplemental tube feedings can promote weight gain and reduce calorie expenditure.
- Adjust caloric density and target volume of enteral feedings.
- Closely monitor weight gain; use World Health Organization growth curves from birth to 24 months.
- Monitor and evaluate feeding behaviors.

adolescence and adulthood. However, for many patients, survival does not necessarily equal cure. Although some lesions, such as valvar pulmonary stenosis or a ventricular or atrial septal defect, may be completely repaired by surgical or catheter-based intervention, even these patients need to be followed by a cardiologist throughout their life. A stenotic pulmonary valve can restenose over time and require reintervention. There might be a residual ventricular septal defect, in which case the patient will require subacute bacterial endocarditis (SBE) prophylaxis for indicated procedures; or the patient may develop ventricular arrhythmias later in life if the surgical repair involved a ventriculotomy.

Infants born with more complex CHD often require lifelong medication, may require multiple reinterventions throughout their life, and may require more aggressive treatment for routine childhood illnesses (eg, viral upper respiratory tract infections) than healthy children. The PCP must carefully follow their somatic growth, developmental milestones, and general state of health in order to provide the best possible care of these complex patients (Box 116-2, Box 116-3, Box 116-4, Box 116-5). Furthermore, many of these patients have significant morbidities after cardiac surgery, such as feeding difficulties (sometimes requiring tube feeding), vocal cord abnormalities, respiratory abnormalities (including the need for tracheostomy in some patients), rhythm abnormalities, and the need for anticoagulation therapy. The PCP is pivotal in providing a stable medical home for these patients and collaborating with the family and multiple subspecialists to coordinate optimal care for the patient. Together, the PCP and subspecialists develop a care plan with the family that addresses the child's specific health and developmental needs and delineates which professional is responsible for managing each of the

**BOX 116-4 High-Calorie Formula**

- Concentrate formula to 24 cal/oz.
- If the patient is receiving human milk, carefully consider constituents added to ensure that adequate protein intake ( $>7\%$  total calories; 2–3 g/kg/day) is maintained while caloric density is boosted.
- Add modular nutrients to increase caloric density above 24 cal/oz:
  - CHO modulars: polycose, Moducal
  - Protein modulars: Beneprotein
  - Fat modulars: Microlipid, medium-chain triglyceride oil, vegetable oil

**BOX 116-5 PredischARGE Checklist: Feeding**

- Demonstrates 3 consecutive days of weight gain (using the same scale) of  $>10$  g per day
- Tolerates the planned home feeding regimen for 3 days with no change in emesis or stool patterns
- Parent/caregiver competence with feeding plan (parent teach-back and demonstration of necessary skills)
  - Formula preparation
  - Feeding regimen including feeding volumes, feeding techniques, tube feedings if needed, home weights, home feeding, and/or monitor logs
- Family has a clearly written feeding plan
  - If mother is breastfeeding, mother has information, lactation support, and supplies needed to breastfeed as well as express milk to sustain milk volume
  - If formula or combination (human and formula) feeding, specify formula type and concentration (cal/oz)
  - Feeding route, frequency, and volumes
  - Weight gain goals
- Family has identified where to get formula and supplies
  - Home health agency
  - Specialty pharmacy
  - Women, Infants, and Children (WIC) Nutritional Program
  - Family to provide
- Family has identified whom to contact for feeding issues and follow-up appointments; there is a need for clear identification of who will actively manage the infant's feeding and nutrition

specific facets of the child's health needs; for example, who will manage the child's nutritional needs to optimize growth.

**Nutrition**

Infants and children with CHD are at higher risk for poor nutrition and slow growth, especially those with

**BOX 116-6 Feeding Problems in Infants With Congenital Heart Disease**

- Lack of or poor coordination of sucking, swallowing, and breathing
- Inefficient suck (feeding fatigue, limited endurance)
- Gastroesophageal reflux disease
- Oral aversion
- Respiratory distress
- Aspiration

**BOX 116-7 Causes of Failure to Thrive in Infants With Congenital Heart Disease**

- Low caloric intake
- Heart failure
- Intercurrent illness, infection
- Gastrointestinal: reflux, malabsorption, obstruction

**BOX 116-8 Feeding and Nutrition "Red Flags"**

- Weight loss of  $>30$  g in 1 day
- Failure to gain 20 g in 3 days
- Intake  $<100$  mL/kg/day
- 2 episodes of vomiting in 24 hours
- Loose stools (change from baseline)

cyanotic CHD. Many of these patients require prolonged intensive care unit stays and prolonged endotracheal intubation in the perioperative period. Furthermore, cardiac surgery carries a risk for recurrent laryngeal nerve damage, which can increase the risk for aspiration or microaspiration with feeding. Studies have shown that up to 48% of infants who have undergone a Norwood procedure (first stage of surgery for HLHS involving reconstruction of the aortic arch using the main pulmonary artery and placement of an aortopulmonary shunt for pulmonary blood flow) have laryngopharyngeal dysfunction. It is well documented that neonates who have undergone surgery for CHD are at risk for feeding difficulties (Box 116-6) and poor weight gain (Box 116-7, Box 116-8).

Cardiopulmonary bypass (CPB), increased RACHS-1 score, and prolonged intubation have been identified as increasing the risk for feeding problems. Infants with comorbidities such as genetic syndromes are also at increased risk for poor feeding and poor growth. The PCP as well as the pediatric cardiologist, should

closely monitor the patient's weight gain and linear growth and adjust the caloric intake as needed. Some patients may require nasogastric or gastric tube feedings at home. This requires parental education and often coordination of home nursing services. Involvement of a nutritionist may be helpful if patients are underweight or overweight.

### Medications

Many children with CHD are on chronic medication. Classes of common long-term medications used in the treatment of these patients include diuretics, antiarrhythmics, anticoagulants, pulmonary vasodilators, afterload reducers, and inotropes. The PCP and the pediatric cardiologist should work together to ensure that the doses are appropriate for the patient's weight and to monitor for medication side effects. Furosemide, a common diuretic used in this population, can cause electrolyte abnormalities and loss of bone density with chronic use. Warfarin, used for anticoagulation in patients with mechanical valves, requires careful monitoring of therapeutic levels and increases the risk for bruising and bleeding. Dietary changes can significantly affect warfarin levels. Careful parent and caregiver education is imperative in patients who are taking this medication. Many antiarrhythmic medications can cause significant electrocardiographic changes (eg, prolonged QTc interval) and are themselves arrhythmogenic. Close monitoring of the patient's electrocardiogram is required, especially during initiation of treatment, and parents should be educated about the signs and symptoms of arrhythmia in infants and children.

### Infections

Children with CHD are at increased risk for morbidity from common childhood infections such as viral respiratory infections. Respiratory syncytial virus (RSV) is an example that has been well studied in this population. Children with hemodynamically significant CHD are more likely to require hospital admission, admission to the intensive care unit, and mechanical ventilation for RSV bronchiolitis than other children with RSV infection. Monthly prophylaxis with palivizumab during the RSV season (November through April) for the first 2 years of life significantly reduces the rate of hospitalization in patients with CHD and should be initiated for patients with significant CHD. PCPs should also ensure that patients with CHD are up to date on their immunizations, including yearly influenza vaccination. Furthermore, some children with CHD have coexisting conditions that lead to immunocompromise (eg, 22q11 deletion syndrome and asplenia in heterotaxy patients). The T-cell abnormalities in 22q11 deletion syndrome may be a contraindication to live virus vaccination; these patients should be referred to an immunologist before administration of these vaccines. Patients with heterotaxy syndrome and asplenia (anatomic or functional) are at increased risk for bacterial infection and should be prescribed prophylactic antibiotics.

Some patients with CHD are at high risk for SBE following dental procedures (or select other procedures)

and should receive antibiotic prophylaxis before these procedures. In 2008, the American Heart Association (AHA) revised its recommendations regarding the patients for whom prophylactic antibiotic therapy is indicated. These recommendations include patients with prosthetic valve material, a previous history of infectious endocarditis, unrepaired (or palliated) cyanotic CHD, cardiac surgery using a prosthetic device or material within 6 months, cardiac surgery with a residual high-velocity shunt, and heart transplantation with valvulopathy. PCPs and pediatric cardiologists should review whether a patient with congenital heart disease should receive SBE prophylaxis and educate the patients and other caregivers accordingly.

## NEURODEVELOPMENTAL ABNORMALITIES IN CHILDREN WITH CONGENITAL HEART DISEASE

It is widely acknowledged that children with CHD have an increased incidence of neurodevelopmental abnormalities compared with the general population. Abnormalities can range from profound brain damage and developmental delay to behavioral disorders such as attention-deficit/hyperactivity disorder and learning difficulty in school, and also include an increased risk for psychiatric disorders. The remarkable improvements in survival after infant cardiac surgery and the increasing numbers of children, adolescents, and adults with repaired CHD have led to an increased awareness and focus on understanding and trying to prevent these adverse neurodevelopmental outcomes. Although we do not have a full understanding of all the factors that contribute to neurodevelopmental abnormalities in patients with CHD, we know that it is multifactorial in origin, with sequelae related to factors including underlying genetic conditions, an increased incidence of preoperative central nervous system abnormalities possibly related to abnormal fetal cerebral blood flow, and postnatal factors such as operative risks, specific intraoperative effects of cardiopulmonary bypass (CPB), and deep hypothermic circulatory arrest, and factors related to the postoperative course.

### Genetic Factors

Although a detailed description of syndromic conditions that are associated with CHD and neurodevelopmental abnormalities is beyond the scope of this chapter, it is important to note that children with a chromosomal abnormality and CHD generally have a worse neurodevelopmental outcome than those with a normal karyotype. Additionally, some syndromes, such as trisomy 21 or 22q11 deletion, have known patterns of neurodevelopmental abnormalities. For example, patients with 22q11 deletion syndrome, which is associated with conotruncal abnormalities such as tetralogy of Fallot or d-TGA, have poor visual-spatial and mathematical skills, can have an IQ ranging from profound disability to an average IQ, and have an increased risk for psychiatric disorders, specifically schizophrenia and schizoid disorder.

With few exceptions, the recent literature suggests that genetic disorders, including trisomy 21, are not a significant risk factor for increased mortality associated with surgical repair of CHD. However, multiple studies have demonstrated that genetic disorders are associated with higher morbidity surrounding cardiac surgery, including increased length of stay, renal insufficiency, postoperative infections, and postoperative respiratory complications. There are few data, however, on neurodevelopmental outcomes specifically in patients with genetic disorders following cardiac surgery for CHD. Visootsak and colleagues published the first study to evaluate the developmental pattern in patients with trisomy 21 who had undergone complete atrioventricular valve repair compared with patients with trisomy 21 and a normal heart. In a small cross-sectional study, motor development was significantly impaired in patients who had cardiac surgery compared to those with a normal heart, but there was no statistically significant difference in cognitive or language abilities.

There may be a genetic component to neurodevelopmental abnormalities in patients with CHD who do not have a described genetic syndrome. A recent study demonstrated that the apolipoprotein E  $\epsilon$ 2 allele is associated with increased behavior problems, restricted behavior patterns, and impaired social interactions in preschool-age children with CHD requiring surgical treatment.

### Gender Differences

Boys have an increased incidence of some forms of CHD, such as HLHS, tetralogy of Fallot, and TGA. Studies on the cellular mechanisms of perinatal brain damage have demonstrated significant male-female differences. Male brains may be more sensitive to cell apoptosis after hypoxic-ischemic injury, whereas female brains may have increased risk for cell apoptosis after oxidative stress injury. Majnemer et al demonstrated that boys with CHD requiring early surgical repair are at increased risk for neuromotor impairments and activity limitations at school entry.

### Central Nervous System Abnormalities

Many newborns with CHD show evidence of neurologic abnormalities preoperatively, suggesting that there are prenatal and perinatal factors involved. Studies have demonstrated that more than 50% of babies with CHD have clinical evidence of neurologic abnormalities before heart surgery. The abnormalities include hypotonia and hypertonia, jitteriness, motor asymmetries, absent suck, poor state regulation, feeding difficulties, seizures, and abnormal somatosensory evoked potentials. Interestingly, these findings were not confined to patients with cyanotic heart disease. These abnormalities are present more commonly in patients with acyanotic heart disease, suggesting that hypoxemia may not be the underlying etiologic cause of the neurologic abnormalities in these patients. There is also radiologic and metabolic evidence of abnormal brain structure and function in neonates with CHD. Preoperative neuroimaging (with magnetic resonance imaging [MRI] or ultrasound) has demonstrated a high incidence of brain malformations (up to

40%–60% of studied infants), including agenesis or dysgenesis of the corpus callosum, holoprosencephaly, microcephaly, lissencephaly, Dandy-Walker malformation, and immature cortical mantle. Studies have reported microcephaly in up to 36% of neonates with CHD. There is also a high incidence of preoperative acquired neurologic injury in these patients, including cerebral atrophy, intraventricular hemorrhage, thromboembolism, infarct, periventricular leukomalacia, and gray matter injury.

Not only brain structure but also brain development is abnormal in patients with CHD. MRI and magnetic resonance spectroscopy studies have demonstrated that term newborns with CHD have levels of brain metabolites that suggest a 1-month delay in brain development. Studies assessing structural evidence of brain development by brain MRI have suggested a similar delay. Preoperative neurologic abnormalities have been significantly associated with long-term neurologic outcome.

Seizures are among the more common acute neurologic events in CHD patients. Preoperative seizures have been documented in neonates before heart surgery, and it is well known that acute postoperative seizures can occur after heart surgery at any age. Postnatal seizures have been reported in 15% to 20% of neonates after heart surgery, with one study demonstrating subgroups of neonates in whom seizures may occur in up to 50%. These subgroups include patients who underwent prolonged deep hypothermic arrest during surgery, patients with associated genetic abnormalities (eg, 22q11 deletion syndrome and trisomy 21), and patients with aortic arch obstruction. There is evidence that seizures in the neonate can indicate lasting physical injury, and the Boston circulatory arrest trial demonstrated that the presence of postoperative clinical seizures after repair of d-TGA was significantly associated with longer-term neurodevelopmental abnormalities and brain MRI abnormalities.

Theories on the etiology of neurodevelopmental abnormalities in patients with CHD include altered cerebral vascular resistance resulting from decreased cerebral blood oxygen content in d-TGA and decreased cerebral perfusion caused by retrograde perfusion of the aortic arch in HLHS. However, neurologic abnormalities are not limited to these lesions and occur in acyanotic and cyanotic CHD. Furthermore, structural brain abnormalities (primarily in the white matter) persist into adolescence. The search for the etiology of neurodevelopmental abnormalities in all patients with CHD is ongoing.

### Preoperative Risk Factors

Clinical risk factors associated with increased preoperative brain injury in newborns with CHD include lower gestational age and lower 5-minute Apgar score. Hemodynamic factors that have been associated with increased preoperative brain injury include decreased carbon dioxide reactivity and low baseline cerebral blood flow. Additionally, preoperative hypoxemia causes damage to the areas of the brain associated with executive functions. Preoperative hypoxemia, severe acidosis, and cardiocirculatory insufficiency have

been correlated with poor long-term neurodevelopmental outcomes.

Balloon atrial septostomy (BAS) is a procedure commonly performed in neonates with d-TGA to improve intracardiac mixing and systemic output in these patients preoperatively. Some studies have reported a significant association between BAS and stroke in these patients; however, other studies have reported that BAS is a confounding factor and that the brain injury is associated with oxygen delivery and time to surgery rather than with the BAS procedure itself.

### Intraoperative Factors

#### Cardiopulmonary Bypass

Cardiopulmonary bypass (CPB) is used in many congenital cardiac surgeries to allow for perfusion of vital organs with oxygenated blood by a mechanical pump circuit. Known neurologic risks of CPB include embolic complications and the activation of systemic inflammatory pathways. Some congenital cardiac surgeries require deep hypothermic circulatory arrest (DHCA) to completely drain the heart of blood and stop circulation through the body. This is achieved by cooling the patient to 60.8°F to 64.4°F (16°C–18°C). Some studies have demonstrated a correlation between the duration of DHCA and adverse neurologic outcome such as seizures and impaired motor function. A safe duration of DHCA has not been definitively demonstrated. Deep hypothermic circulatory arrest times longer than 45 to 60 minutes have been associated with mortality, neuromotor deficits, and global developmental delay. The Boston Circulatory Arrest Trial investigated the use of DHCA in neonates undergoing surgical repair of d-TGA. Infants undergoing DHCA for more than 40 minutes had an increased incidence of postoperative seizures compared to those with DHCA duration of less than 40 minutes. The incidence of postoperative seizures in patients with DHCA duration less than 40 minutes was not significantly different than in those patients undergoing regular CPB. Long-term neurodevelopmental follow-up of these patients showed that DHCA is associated with worse neurodevelopmental outcomes at 8 years of age than is hypothermic continuous low-flow bypass. However, other studies have found different results in other groups of patients. Fuller et al reported that in a cohort of patients with CHD without aortic arch obstruction, there was no significant association of DHCA with neurodevelopmental outcome at 4 years of age.

Surgical techniques are evolving to try to maximize neuroprotection in patients undergoing surgical repair for CHD. Hybrid strategies have been developed that avoid CPB in neonates with HLHS. Regional low-flow cerebral perfusion techniques allow brain perfusion without DHCA in aortic arch repairs, but a single-center comparison of the 2 techniques did not demonstrate an overall significant difference in primary endpoints of neurodevelopmental outcome (intelligence, reading, mathematics). Patients who underwent DHCA during repair of d-TGA had worse performance on motor function testing, visual-motor tracking, and phonologic awareness than patients

who underwent low-flow CPB; however, patients who underwent CPB had more impulsivity and worse behavior than those who underwent DHCA. Pediatric cardiothoracic surgeons, anesthesiologists, and perfusionists are continuing to explore new techniques that may continue to improve neuroprotection during CPB and DHCA.

### Anesthesia

There is emerging evidence linking neonatal and pediatric exposure to anesthesia with neurodevelopmental abnormalities. Animal models have demonstrated that exposing the developing brain to anesthetic agents causes neurotoxicity and abnormal neurobehavioral responses in adult animals. Flick et al demonstrated that, in humans, repeated anesthesia exposure before age 2 is an independent risk factor for the later development of learning disabilities. There are still limited data in humans, but this is a focus of research and scientific discussion.

### Postoperative Risk Factors

The postoperative neurologic risk in patients who have undergone surgical repair of CHD can be divided into the immediate and long-term postoperative periods. In the immediate postoperative period, hypotension and hypoxia are independent risk factors for periventricular leukomalacia. Evidence also suggests that the increasing complexity of the postoperative course (measured by length of intensive care unit stay and hospital stay) is associated with poorer tests of cognitive function and development.

Sick euthyroid syndrome is common after congenital heart surgery and is more marked in increasingly complex cases. In preterm infants, transiently low thyroid levels early in life are associated with poorer motor function, learning disabilities, and cerebral white matter damage. It is possible that postoperative thyroid abnormalities are a contributing factor to postoperative neurologic risk in CHD patients.

There are also long-term factors that place these children at increased risk for neurologic damage. Many patients who undergo congenital heart surgery during infancy or childhood require cardiac catheterization later in life. Although the risk associated with cardiac catheterization is generally lower than for CPB surgery, a 0.38% incidence of neurologic events (primarily seizure and stroke) in children undergoing cardiac catheterization has been described. If intravenous contrast is used for angiography, there is a risk for contrast toxicity, which is also associated with seizures. Children who have poor left ventricular function, arrhythmias, or prosthetic left-sided valves are at increased risk for the development of intracardiac thrombi, which can embolize to the brain. Furthermore, if there is a residual intracardiac communication such as an atrial septal defect or a Fontan fenestration, paradoxical emboli can cross from the systemic venous circulation to the brain. If patients with a prosthetic valve are managed with anticoagulation, over-anticoagulation can occur caused by dietary changes or medication interaction. This increases the risk for hemorrhagic stroke. Finally, CHD

is the most common predisposing cause of brain abscess, which can result from septic emboli in endocarditis.

### **Neurodevelopmental Outcome in Children With Congenital Heart Disease**

Children who have undergone surgical repair or palliation for CHD have lower scores on many aspects of neurodevelopmental and functional testing. As these children grow older, they have more difficulty in school as well as an increased risk for inattention and hyperactivity and psychiatric disorders. Although this is widely acknowledged in academic settings, a study from Canada suggested that the degree of functional limitation in day-to-day life is underestimated in the clinical (community) setting. Insufficient awareness of these developmental and educational limitations may lead to these children receiving fewer support services, such as occupational and speech therapy, than they truly require.

Although it is difficult to generalize across the heterogeneous population of infants who have had surgery for CHD, it has been well demonstrated that these children have significant impairments in many aspects of neurodevelopment compared with the general population. During infancy, patients commonly demonstrate global developmental delay, with more profound abnormalities in gross and fine motor skills. These deficits persist into childhood, with school-age patients demonstrating delays in adaptive, fine, and gross motor skills that manifest as difficulties with balance, coordination, and manual dexterity. These children also exhibit behavior problems such as inattention and shyness, in addition to poor visual-spatial skills, poor expressive language, IQ in the low-normal range, and poor socialization skills.

Parents of children with CHD report poorer school performance, more problems with grade retention, and more social, behavioral, and attention difficulties than children without CHD. Child self-reports were similar to children without CHD, with the exception that children with CHD reported increased depressive symptoms. A recent meta-analysis of the psychological and cognitive functioning of children and adolescents with CHD reported an increased risk for total internalizing behaviors and, to a lesser degree, externalizing problem behaviors, as well as poorer cognitive performance, that remained stable over time and age groups. Perceptual organizational and visual-spatial abilities were also impaired.

The heterogeneity of CHD has resulted in certain subsets of patients being studied in greater detail in regard to neurodevelopmental outcome. These include children with d-TGA and patients with single-ventricle physiology requiring Fontan palliation, especially those with HLHS.

#### ***d-Transposition of the Great Arteries***

The aforementioned Boston Circulatory Arrest Trial follows patients who have undergone an arterial switch procedure for d-TGA and has reported the neurodevelopmental outcomes for these patients at ages 1, 4, and 8 years (with the 16-year evaluation ongoing). At 1 year of age, patients undergoing DHCA

rather than low-flow CPB had lower motor development scores and more neurologic abnormalities such as seizures or abnormalities on examination. At 2.5 years of age, patients who underwent DHCA demonstrated slower expressive language development, and at 4 years of age they had lower fine and gross motor scores, more abnormalities in speech and language, and more oromotor apraxia. All patients (regardless of treatment group) demonstrated more neurodevelopmental abnormalities than healthy children and had mean full-scale IQ scores 0.5 standard deviation below the normal population mean. At age 8 years, the neurodevelopmental abilities of the entire group of children followed (regardless of treatment group) included decreased academic performance and poorer fine motor function, visual-spatial skills, and working memory. These children demonstrated poor executive function with difficulties in task planning and task completion, sustained attention, and more complex language and communication skills. Bellinger has proposed that some of the patterns of neurodevelopmental abnormalities seen in these patients can be understood as “theory of mind deficits” that are expressed as poor social cognition. These patients have difficulty describing their own emotional states as well as identifying other people’s feelings and emotions (“reading” people). This decreased ability to interpret social information may lead to difficulties in forming and maintaining social relationships and contribute to poor psychosocial functioning in general.

#### ***Single Ventricle (Including Hypoplastic Left Heart Syndrome)***

Children with HLHS are reported to have the highest risk for neurodevelopmental abnormalities of all patients with CHD. A recent review of HLHS describes a pattern of dysfunction in these patients that includes mild cognitive impairment, impaired social interactions, poor communication skills, inattention, impulsivity, and impaired executive function. Studies demonstrate low psychomotor development and low motor development scores in these patients at 1 and 2 years of age. With a change in surgical practice from the Blalock-Taussig shunt to the right ventricle-to-pulmonary artery shunt at one institution, there was an improvement in psychomotor development at 2 years of age. Risk factors for poor neurodevelopmental outcome include seizures and longer bypass time.

### **QUALITY OF LIFE IN CHILDREN WITH CONGENITAL HEART DISEASE**

The perceived health status of children after open heart surgery is generally comparable to that of the general population despite increased reporting of problems with learning, behavior, and socialization. However, when focusing on social and emotional functioning, parents of children with CHD describe their children as more withdrawn, having more social problems, and engaging in fewer activities compared with parents of children with an innocent murmur. Parents of children with CHD have a high risk for feeling distress and hopelessness. In mothers of infants with CHD, there is a correlation between the severity

of CHD in the child and maternal symptoms of depression and anxiety at 6 and 18 months postpartum. Fathers of infants undergoing surgery for CHD report conflicting reactions of joy, sadness/loss related to the illness, fear of the infant's vulnerability and possible death, and a drive to maintain control and be strong for others while undergoing intense emotions themselves. Studies suggest that, as with other serious childhood illnesses, severe CHD has a significant psychosocial effect on the family, with an underlying genetic disorder in the patient and poorer perceived social support being associated with increased familial effects in 1 study. The effects on the family are not limited to parents and the patient; Janus and Goldberg described effects on healthy siblings' behavior, demonstrating that the family's accommodation of the patient's illness seemed to increase the risk for behavioral problems in the sibling. Discussion of the psychosocial effects of having a child with CHD is important for the PCP to gain a full understanding of the effect on the whole family as well as to try to provide support services whenever possible.

Adult patients with CHD do not have significantly different quality-of-life scores from the general population, based on self-report questionnaires. However, these patients have a high rate of medical complications and psychosocial problems that may not be accounted for by the health-related quality of life measures studied. Many of these patients report decreased exercise intolerance and corresponding limitation of their activities. The psychosocial problems that are often encountered by this population include disability benefits, problems with life or health insurance, and concerns about having children. A single large Canadian center reported that adults with CHD report moderate to extreme concern about physical activity, insurance, assuming increased health responsibility, diet, mental health, and their mortality.

## EXTENDING CARE INTO ADULTHOOD

There are currently more than 1 million adults with CHD in the United States, and this number is rising exponentially. Fewer than half of these patients are seen by subspecialist providers in the recently emerged field of adult CHD. The AHA published a scientific statement on the best practices in managing the transition from adolescence to adulthood for patients with CHD that focuses on maintaining uninterrupted health care for these patients and optimizing their quality of life and life expectancy.

Recent guidelines recommend individualizing the transition process for each patient and starting to prepare the patient for transition to adult care during adolescence. The pediatrician and pediatric cardiologist should initiate discussions about risk-reducing behaviors, including the cardiac risks of illicit and prescription drug, alcohol, and tobacco use; nutrition counseling; and discussions about contraception with female patients. Pregnancy and delivery involve major hemodynamic changes in the female body and confer an increased risk to a woman with CHD. Furthermore, there is an increased risk for CHD in the fetus with a first-degree relative with CHD. The management of an adolescent with CHD should include counseling about

these risks during discussions of sexual health and contraception.

## SUMMARY

The diagnosis and treatment of congenital heart disease has made rapid advances over the last half-century. Many children born with complex CHD now survive into adulthood. An understanding of the morbidities associated with congenital cardiac surgery and the long-term outcomes of these diseases is important to provide a stable and comprehensive medical home for these often complex patients. Collaboration and cooperation with multiple medical subspecialists is often required to coordinate problems that may range from mild developmental delay to respiratory and feeding abnormalities requiring mechanical support, to ongoing cardiac abnormalities. Furthermore, referral to support services for possible neurodevelopmental difficulties and psychosocial and behavioral problems may be required, both for the patient and for members of the patient's family. For adolescents, the PCP should play a pivotal role in the transition to adult care and discussions about risk-reducing behaviors. The PCP, as the fulcrum of the medical home, is in a unique situation to ensure that comprehensive care is provided to these patients.

## INFANTS WITH MALFORMATIONS OF THE TRACHEOBRONCHIAL TREE AND DIAPHRAGM

### Tracheobronchomalacia

The term *malacia*, derived from the Greek *malakia*, means softness, and in medical terminology usually refers to cartilage or bone. Tracheobronchomalacia therefore is a softness or weakness of the cartilage in the trachea and bronchi. Clinically, tracheobronchomalacia usually manifests as expiratory stridor and cough caused by collapse of the airway lumen, especially during states in which the intrathoracic pressure is greater than the intraluminal pressure (eg, during a Valsalva maneuver). However, there are some cases of cervical or extrathoracic tracheobronchomalacia in which symptoms manifest during inspiration. Tracheobronchomalacia is the most common congenital anomaly of the trachea and is generally classified as primary (congenital) or secondary (acquired).

Primary tracheobronchomalacia can be further divided into isolated or syndromic etiologies. Isolated tracheobronchomalacia can be seen in otherwise healthy full-term infants but more commonly affects premature infants. It is thought to be caused by immaturity of the tracheobronchial cartilage, either because of preterm birth or because of structural (developmental) immaturity of the tracheal tissue. In term infants, the symptoms usually present during the first few weeks or months of life and often demonstrate improvement by 1 year of age as the airway smooth muscle increases the tone of the trachea. Tracheobronchomalacia is thought by some investigators to be part of the spectrum of bronchopulmonary dysplasia in preterm infants, with reported incidences of 25% to 86% in different series. Conditions associated with syndromic primary tracheobronchomalacia

include genetic abnormalities (eg, Down syndrome, 22q11 deletion syndrome, CHARGE syndrome, VACTERL association, mucopolysaccharidoses, Diamond-Blackfan syndrome, and Pierre Robin sequence), chondrodysplasias, tracheoesophageal fistula, and esophageal atresia.

Secondary tracheobronchomalacia is caused by degeneration of normal tracheal and bronchial cartilage. Tracheomalacia can result from prolonged ventilation, either from endotracheal intubation or from tracheostomy. Prolonged intubation is a common cause of secondary tracheomalacia, with increased airway pressure from mechanical ventilation and increased infection risk as additive insults to the tissue. This contributes to the risk for tracheomalacia in preterm infants requiring prolonged intubation as well as in infants and children requiring multiple intubations, prolonged intubation, or tracheostomy (eg, cardiac abnormalities requiring cardiac surgery, respiratory failure, or organ transplantation). Thus, premature infants, who often require endotracheal intubation, are at risk for both primary and secondary tracheobronchomalacia. Tracheostomy, as well as endotracheal intubation, is a risk factor for secondary tracheobronchomalacia with potential involvement of the stoma site, the cuff site, and the tube tip site. External compression of the airway is another common cause of secondary tracheobronchomalacia. This can be caused by a vascular abnormality such as a double aortic arch, a vascular ring, or an abnormal take-off of the innominate artery, or from left atrial enlargement as is seen in severe dilated cardiomyopathy. Other causes of external airway compression include mediastinal masses (eg, thymoma, ectopic thyroid, teratoma, bronchogenic cyst, and lymphoma), skeletal deformation (eg, scoliosis), and infection (eg, abscess).

Treatment of tracheobronchomalacia varies according to its etiology. As mentioned earlier, some forms of idiopathic tracheobronchomalacia resolve over the first 1 to 2 years of life as the tracheal smooth muscle gains tone and the tracheal cartilage strengthens. Symptomatic treatment during the first 2 years can include humidified oxygen, pulmonary toilet, and treatment of respiratory infections. In patients in whom the above measures are inadequate, continuous positive airway pressure can be an effective treatment that avoids the need for more invasive measures. However, in some patients, the disease is persistent or causes severe life-threatening episodes and therefore merits interventional therapy. Historically, the therapy for these patients has been tracheostomy and mechanical ventilation, but these treatments confer significant morbidity (eg, infection risk, recurrent bronchospasm, and difficult decannulation) as well as the inherent risk for worsening tracheomalacia. In recent years, however, new surgical techniques have been developed that show promise in the treatment of this disease. Aortopexy, in which the anterior aortic wall is sutured to the sternum, thus widening the anterior-posterior dimension of the tracheal lumen (because the anterior wall of the trachea is adherent to the posterior wall of the ascending aorta), has been demonstrated as an effective treatment for severe tracheomalacia. Internal tracheal and/or bronchial stents,

deployed by bronchoscopy, have also been developed and require a less interventional approach.

### Tracheoesophageal Fistula and Esophageal Atresia

Tracheoesophageal fistula (TEF) is a congenital connection between the tracheal tree and the esophagus (either proximal or distal). Esophageal atresia (EA) is a complete interruption of the esophagus with no connection of the esophagus with the stomach. TEF and EA can occur separately but often occur together and affect 1 in 2,400 to 4,500 people. EA and TEF are seen in combination with other congenital defects in 25% of patients, most commonly cardiac anomalies (35%), genitourinary anomalies (24%), other gastrointestinal anomalies (24%), skeletal anomalies (13%), and central nervous system anomalies (10%); when all the above defects occur together, this is termed the VACTERL association. Despite significant advances in the field of fetal medicine, the antenatal diagnosis of EA and TEF remains challenging, with only 10% to 40% of cases diagnosed on prenatal ultrasound. Neonates with EA and TEF have excessive oral secretions and feeding and respiratory difficulties. EA and TEF are treated with surgical repair and are commonly repaired during early infancy. However, EA with a distal TEF requires urgent neonatal surgery because of a high risk for aspiration pneumonitis. Some severe cases may require multiple procedures (eg, esophageal lengthening procedures) and delayed esophageal-gastric anastomosis. Surgical survival rates for low-risk patients with EA and TEF are excellent; however, survival rates decrease significantly in higher-risk populations. Prematurity, associated abnormalities (especially cardiac and chromosomal abnormalities), and prenatal diagnosis have been shown to have predictive value in overall outcome. Current surgical survival rates have been reported as 98% for patients with birth weight above 1,500 g and no major cardiac anomalies, 82% for patients with a birth weight of less than 1,500 g or a major cardiac anomaly, and 50% for patients with a birth weight of less than 1,500 g and a major cardiac anomaly. Surgical correction can be performed with an open or a thoracoscopic approach and is successful in most cases, but recurrence of the TEF occurs in about 9% of cases. In addition to surgical mortality risk, there are a number of morbidities that affect long-term outcome in patients with EA and TEF.

### Gastrointestinal Complications

Gastrointestinal complications are common in patients with EA and TEF. Dysphagia and gastroesophageal reflux are some of the more common complications in this population. Dysphagia with abnormal esophageal peristalsis is seen in up to 75% to 100% of children and young adults with EA and is reported to persist in 53% to 92% of adult patients. Abnormal esophageal peristalsis may cause failure to thrive or frequent aspiration because of poor feeding and can lead to esophageal obstruction requiring surgical intervention. Gastroesophageal reflux disease (GERD) occurs in 35% to 58% of children with EA and TEF and can lead

to esophageal strictures and frequent aspiration (which can lead to permanent lung damage). Many of these patients respond to medical antireflux therapy, but 13% to 25% of patients require Nissen fundoplication for treatment of GERD. Anastomotic leak is an early postoperative complication, reported in up to 17% of patients, that can have serious long-term consequences. Essentially all anastomotic leaks (95%) resolve either spontaneously or with pleural drainage, but esophageal stricture and even recurrence of the TEF can occur in 50% of cases. The rate of postoperative esophageal stricture varies in the literature from 6% to 40% of patients, and is more common after repair of an atretic gap greater than 2.5 cm and in patients with GERD. They often present with gastrointestinal symptoms, such as poor feeding and emesis, but can present with recurrent postaspiration pneumonia. The usual treatment for esophageal stricture involves repeated dilation.

### **Respiratory Complications**

Patients with EA and TEF have a high incidence of respiratory symptoms, including recurrent pneumonia, aspiration, chronic cough, and choking, gagging, and cyanosis with feeding. These patients often require hospitalizations because of respiratory disorders. Tracheomalacia is also a common respiratory finding in patients with EA and TEF, but it is clinically significant only in 10% to 20% of patients. In severe cases of tracheomalacia, tracheal collapse occurs during expiration and usually causes a hoarse cough, but it can sometimes result in life-threatening spells with apnea and cyanosis. Patients with these acute life-threatening spells can undergo surgical treatment with aortopexy to maintain patency of the tracheal lumen. Aspiration, tracheomalacia, sudden infant death syndrome, and reactive airway disease are reported as causes of death in 60% of late deaths in patients with EA and TEF.

### **Congenital Diaphragmatic Hernia**

Congenital diaphragmatic hernia (CDH) is a defect in the diaphragm that results in herniation of abdominal contents into the thorax. It occurs in approximately 1 in 2,400 to 3,000 live births and more commonly involves the left hemidiaphragm (75%–85%). Pulmonary hypoplasia of the ipsilateral lung is the usual associated finding, caused by the presence of abdominal organs in the thorax during fetal development. Malrotation of the intestine is also often present. CDH can occur in isolation or in association with other findings, such as omphalocele, CHD, trisomy 21, trisomies 13 and 18, Brachmann-de Lange syndrome, and Pallister-Killian syndrome (tetrasomy 21p mosaicism).

CDH was considered to be a surgical emergency in the newborn until the early 1990s and had an overall survival rate of approximately 50% to 55%. The treatment in that era was aggressive ventilation with hyperventilation and high peak pressures, with salvage measures such as ECMO and high-frequency oscillation ventilation (HFOV). However, survival was not improved by any of these measures, and it was not until the implementation of “lung preservation” or gentle ventilation strategies in the mid-1990s, with

changes to both resuscitation and ventilation techniques, that overall survival rates improved. This gentle ventilation approach includes allowing spontaneous breathing and permissive hypercapnia combined with elective surgical repair, and the avoidance of chest tube placement during repair. Survival rates in the current era are now higher than 70% to 80% and have been reported above 90% by some centers. Factors that are associated with increased mortality include severity of pulmonary hypertension at 1 month of life, birth weight and gestational age, and need for ECMO therapy. Newer techniques such as thoracoscopic repair of CDH and fetal interventions to correct CDH are ongoing but have not been conclusively demonstrated to be superior to conventional repair.

As has been seen with congenital heart disease, significant reductions in mortality rates spurred interest in investigating and minimizing the morbidities associated with the treatment. The survival of larger numbers of patients with CDH and the recognition of the multisystem morbidities seen in these patients has led to the development of multidisciplinary follow-up centers that follow standardized protocols for long-term evaluation and treatment.

### **Neurodevelopmental Morbidity**

Studies of children who survive repair of their CDH demonstrate anatomic neurologic abnormalities in 33% to 48% of patients, including periventricular leukomalacia and intracranial hemorrhage. Patients with repaired CDH also have functional neurodevelopmental abnormalities, such as neuromotor delay, hypotonia, and language delay. Risk factors for neurodevelopmental abnormalities at 2 years of age include right-sided CDH, ECMO therapy, intrathoracic liver, Gore-Tex patch repair (as opposed to direct repair), hypotonicity, and oxygen use at day of life 30. School-age CDH survivors (including children who did not require ECMO) demonstrate an increased incidence of learning disabilities compared with the normal population. Hearing loss, especially sensorineural, occurs in a large percentage of survivors of CDH, although the pathogenesis of the hearing loss is unknown.

### **Pulmonary Morbidity**

Although patients with CDH have abnormal pulmonary function tests at 1 year of age, the abnormalities normalize in most patients by 2 years of age. However, patients with CDH remain at risk for recurrent respiratory infections, asthma, restrictive lung disease, and pulmonary hypertension.

### **Gastrointestinal Morbidity**

Most patients with repaired CDH have documented GERD by pH probe and impedance testing, although only about half of patients report GERD symptoms. Risk factors for severe GERD include Gore-Tex patch repair, intrathoracic liver, HFOV, and ECMO support. Some patients have esophageal dysmotility as well as GERD and require treatment with promotility medication as well as antacid therapy. Studies have shown that GERD persists into adulthood in many survivors of CDH and confers an increased risk for the development of premalignant Barrett esophagus in these

patients. With this knowledge, some centers are aggressively treating GERD with surgical therapy such as gastric fundoplication at the time of CDH repair.

### **Musculoskeletal Morbidity**

Musculoskeletal abnormalities in patients with CDH repair include chest wall deformities (eg, pectus excavatum and pectus carinatum) and scoliosis. Centers have tried many different materials for patch repair of CDH, but no single material has been demonstrated to be markedly superior in preventing chest wall deformities or hernia recurrence.

## **NEONATES TREATED WITH ADVANCED THERAPIES FOR CARDIORESPIRATORY FAILURE OR SUSPECTED HYPOXIC ISCHEMIC ENCEPHALOPATHY**

### **Respiratory Failure in Term and Late Preterm Infants**

Severe respiratory failure can develop in full-term and late preterm infants born with CDH or because of persistent pulmonary hypertension of the newborn (PPHN). PPHN may develop in response to meconium aspiration syndrome; other primary pulmonary pathology such as primary pulmonary hypertension, pneumonia, and respiratory distress syndrome; or secondary to pulmonary air leak or sepsis. In addition to respiratory support that includes noninvasive and invasive ventilation, oxygen therapy, and inhaled nitric oxide to reverse the pulmonary hypertension, a small percentage of infants will require treatment with ECMO. Also referred to as extracorporeal life support, ECMO is a form of prolonged extracorporeal cardiopulmonary bypass used in patients with acute reversible respiratory or cardiac failure. ECMO involves (1) draining venous blood to allow (2) removal of CO<sub>2</sub> and (3) addition of O<sub>2</sub> through an artificial lung (bypass circuit) that then (4) returns warmed, oxygenated blood to the circulation, thus (5) allowing normal aerobic metabolism while the lung “rests” (Figure 116-2). There are 2 types of ECMO, venovenous and venoarterial. Absolute contraindications for treatment of neonatal

respiratory failure with ECMO include a lethal chromosomal disorder, irreversible brain damage, and grade III or greater intraventricular hemorrhage. Relative contraindications include irreversible organ damage (unless patient is considered to be an organ donor), weight less than 2 kg, and gestational (or postmenstrual) age younger than 34 weeks, because of the increased incidence of intracranial hemorrhage.

### **Morbidity and Mortality Associated With Extracorporeal Membrane Oxygenation**

Survival rates vary among infants based on the underlying cause of the cardiorespiratory failure. Data from the Extracorporeal Life Support (ELSO) Registry in Ann Arbor, Michigan, reveal that among neonates treated with ECMO because of respiratory failure, 85% survive ECMO treatment, but only 75% ultimately survive to hospital discharge or transfer to another care facility. The group of neonates treated with ECMO because of respiratory failure is quite heterogeneous. Patients treated with ECMO because of meconium aspiration syndrome, primary pulmonary hypertension, respiratory distress syndrome, pneumonia, or massive air leak recover in more than 80% of cases. This is in contrast to infants treated with ECMO because of CDH or sepsis. Survival in this group of babies is approximately 60%. Review of neonatal ECMO outcomes reported to the ELSO registry for infants treated between 2005 and 2010 revealed that 20% of the infants supported with ECMO had neurologic complications. Patient factors (gestational age and birth weight), pre-ECMO illness severity (metabolic acidosis), and use of venoarterial ECMO are associated with increased neurologic complications and mortality risk.

The United Kingdom Collaborative ECMO Trial reported survival rates and health and developmental outcomes at ages 1, 4, and 7 years for a group of infants with respiratory failure born between 1993 and 1995 who were treated with either conventional medical management or ECMO. Among children treated with ECMO who recovered, 70% were reported to have normal health and cognition at age 7 years. Areas of difficulty included spatial abilities (pattern construction and design recall), reading comprehension, fine motor skills, auditory processing, communication difficulties that can interfere with learning, and verbal and nonverbal memory. Neuromotor development was normal in 40% of ECMO-treated survivors and impaired in 40% of the group. Approximately 7% of these children were classified as having milder impairments on standardized testing. Behavioral problems were reported in 18% of ECMO-treated children. The subsequent health of ECMO-treated children was better than that of children treated with conventional medical therapy: 11% of ECMO-treated children reported wheezing in the preceding 12 months, and 25% used an inhaler in comparison with conventionally treated children, of whom one-third wheezed and 40% used an inhaler at age 7 years. Similar outcomes have been reported by investigators from the Netherlands: 20% of children exhibited a combination of motor, cognitive, and behavioral problems at age 5 years,

**Figure 116-2** Infant receiving extracorporeal membrane oxygenation.

whereas 12% demonstrated only isolated cognitive or behavioral problems.

An important sequela following ECMO treatment is sensorineural hearing loss (SNHL) that is progressive and often delayed in onset. Reported rates of SNHL vary between 3% and 42%. Permanent hearing loss (PHL) is highest among infants with CDH. One factor that contributes to development of PHL is therapy with ototoxic medications often used in the treatment of infants in severe respiratory failure. Duration of medication use and possibly also therapy with neuromuscular blockers contributes to PHL. In addition, clinical seizure activity before ECMO and the duration of ECMO therapy are significantly associated with SNHL.

### **Follow-up Health and Developmental Screening and Surveillance**

Recommended follow-up care for infants treated with ECMO who recover from severe neonatal respiratory failure includes enhanced surveillance and screening as detailed in Table 116-3.

### **Neonates Treated for Suspected Hypoxic Ischemic Encephalopathy**

Hypoxic ischemic encephalopathy (HIE) is an important cause of brain injury in the newborn and can result in lifelong health and neurodevelopmental consequences. Perinatal hypoxia may result in long-term neurologic complications varying from mild behavioral deficits to epilepsy, severe cognitive impairment, and cerebral palsy. HIE occurs in 1 to 6 infants per 1,000 live full-term births in developed countries; rates are higher in low- and medium-resource countries. Of affected newborns, 15% to 20% will die in the postnatal period, and an additional 20% to 35% will exhibit childhood disabilities, including cognitive impairments, visual motor or visual perceptive dysfunction, increased hyperactivity, cerebral palsy, and epilepsy. Later outcomes are related to disease severity (Table 116-4). Among infants who die before NICU discharge, death is often because of multisystem organ failure and redirection of care. Deaths of infants after hospital discharge are most commonly caused by complications from aspiration pneumonia and systemic infection. Survivors of HIE often experience significant feeding difficulties and growth problems during the early months after NICU discharge. Factors associated with subsequent cerebral palsy are listed in Box 116-9.

### **Pathogenesis**

The outcomes of HIE result in significant burdens for patients, families, and society. The neuropathologic features of perinatal HIE vary considerably with the gestational age of the infant, the nature of the insult, and treatments provided. The development of brain injury after a hypoxic ischemic insult is an evolving process that is initiated during the acute insult and extends into a reperfusion phase. The principal pathogenetic mechanism underlying neurologic damage in HIE resulting from hypoxemia or ischemia is deprivation of required brain glucose and oxygen supplies. This causes energy failure and initiates a cascade of

biochemical events leading to cell dysfunction and cell death. This initial injury is compounded by a subsequent reperfusion injury that often worsens brain damage.

### **Treatment Strategies**

Treatment during the immediate newborn period is primarily supportive. Therapy includes correction of hemodynamic and pulmonary disturbances (hypotension, metabolic acidosis, and maintenance of adequate ventilation), correction of metabolic abnormalities (glucose, calcium, magnesium, and electrolytes), treatment of seizures if present, and monitoring for other organ system dysfunction, such as acute kidney injury. Maintenance of adequate ventilation and perfusion is a central component of supportive care. Oxygen deprivation may lead to loss of normal cerebrovascular autoregulation with subsequent neuronal and white matter injury. The presence of seizures, typically beginning within the first hours after birth, may potentiate the underlying brain injury and predict a poor outcome of HIE. The incidence of seizures in neonates with moderate or severe HIE is reported to range from 22% to 64%.

A number of neuroprotective drugs (*N*-acetylcysteine, allopurinol, magnesium, glutamate receptor blockers, and erythropoietin) are being studied to evaluate their value in protecting neonates from the neurologic sequelae following a hypoxic ischemic insult. However, the most potent and promising intervention to prevent brain injury is mild hypothermia. Reducing the body temperature slightly [3.6°F to 7.2°F (3°C–5°C)] below the normal level, to 91.4°F to 95°F (33°C–35°C) (mild hypothermia), reduces cerebral injury, decreases brain energy utilization, reduces the size of infarcts, and ameliorates neuronal cell loss, preserving hippocampal structure. Neonatal therapeutic hypothermia may be achieved through the application of head (brain) cooling (Figure 116-3), or through whole-body cooling with placement of a hypothermia blanket under the infant. Hypothermia improves neurologic outcomes after moderate asphyxia. The beneficial effects of mild hypothermia occur at multiple sites in the cascade to cell death. Hypothermia should be initiated within 6 hours of birth before the onset of delayed energy failure in brain tissues.

Early initiation of hypothermia in infants improves survival and reduces the rate of disability of those survivors. Several clinical trials currently ongoing in the United States and Europe are investigating the efficacy of later initiation of mild hypothermia after 6 hours of age, and other studies are evaluating the effects of moderate hypothermia. During treatment with mild therapeutic hypothermia, neonates typically are also treated with sedatives, analgesics, antiepileptic drugs, and antibiotics as adjunctive therapy to selective brain or whole-body cooling. The benefits of antiepileptic medications are unclear, although Glass et al have reported improved outcomes among infants treated with phenobarbital in the presence of clinical seizures. There is evidence of delayed clearance of drugs administered to infants during hypothermia that are metabolized by cytochrome P-450 enzymes.

Table 116-3

## Recommendations for Enhanced Surveillance and Screening

	BEFORE DISCHARGE	1-3 MO AFTER BIRTH	4-6 MO AFTER BIRTH	9-12 MO AFTER BIRTH	15-18 MO AFTER BIRTH	ANNUAL THROUGH 16 YR
<b>Weight, length, head circumference</b>	X	X	X	X	X	X
<b>Chest radiograph</b>	X	If patched	If patched	If patched	If patched	If patched
<b>Pulmonary function testing</b>						
<b>Childhood immunizations</b>	As indicated throughout childhood	X	X	X	X	X
<b>RSV prophylaxis</b>	RSV season during the first 2 yr after birth if evidence of CLD	X	X	X	X	X (through 24 mo age if CLD present)
<b>Echocardiogram and cardiology follow-up</b>	X	If previously abnormal or if on supplemental O <sub>2</sub>	If previously abnormal or if on supplemental O <sub>2</sub>	If previously abnormal or if on supplemental O <sub>2</sub>	If previously abnormal or if on supplemental O <sub>2</sub>	If previously abnormal or if on supplemental O <sub>2</sub>
<b>Head CT or MRI</b>	If (1) abnormal finding on head ultrasound; (2) seizures/abnormal neurologic findings <sup>a</sup> ; or (3) ECMO or patch repair	As indicated	As indicated	As indicated	As indicated	As indicated
<b>Hearing evaluation</b>	Auditory evoked brain response and otoacoustic emissions screen	X	X	X	X	Every 6 mo until 3 yr, then annually until age 5 yr
<b>Developmental screening evaluation</b>	X	X	X	X	X	Annually until age 5 yr, repeat at age 8 yr
<b>Neurodevelopmental evaluation<sup>b</sup></b>	X	X	X	X	X	Annually until age 5 yr, repeat at age 8 yr
<b>Assessment of oral feeding problems</b>	X	X	X	X	X	If oral feeding problems
<b>UGI study, pH probe, and/or gastric scintiscan</b>	Consider for all patients	If symptoms	If symptoms	If symptoms	If symptoms	If symptoms
<b>Esophagoscopy</b>		If symptoms	If symptoms	If symptoms	If symptoms	If symptoms
<b>Scoliosis and chest wall deformity screening (PE, chest radiograph, and/or chest CT)</b>				or if abnormal gastrointestinal evaluations		X

CLD, chronic lung disease; CT, computed tomography; MRI, magnetic resonance imaging; PE, pulmonary embolism; RSV, respiratory syncytial virus; UGI, upper gastrointestinal.

<sup>a</sup>Muscle weakness, hypotonia, hypertonia, or other abnormal neurologic sign or symptom.

<sup>b</sup>The neurosensory tests performed and the frequency of surveillance among infants with CDH may differ because of variability in neurologic, developmental, and physical impairments. Follow-up should be tailored to each infant.

**Table 116-4** Outcomes of Neonatal Encephalopathy Caused by Hypoxic Ischemic Injury

Mild encephalopathy	No increased risk for motor or cognitive disability 15%–20% exhibit significant learning disabilities
Moderate encephalopathy	30%–50% exhibit serious sequelae 10%–20% exhibit minor disabilities Significant motor deficits Memory impairment Visual, motor, or visual perceptive dysfunction Increased hyperactivity Delayed school readiness
Severe encephalopathy	Increased risk for death (75% die), cerebral palsy, and IQ <70 70%–80% experience serious sequelae 10%–20% exhibit moderate to serious sequelae

Adapted from de Vries LS, Jongmans MJ. Long-term outcome after neonatal hypoxic-ischaemic encephalopathy. *Arch Dis Child Fetal Neonatal Ed.* 2010;95:F220–F224.

### BOX 116-9 Factors Associated With Later Cerebral Palsy

- Severe encephalopathy
- More than 1 neonatal seizure
- Need for phenytoin
- Abnormal neurologic findings at NICU discharge
- Antiepileptic medication at discharge

**Figure 116-3** Head cooling to reduce the risk for brain injury in a baby with hypoxic ischemic encephalopathy.

This may prolong the effects of specific therapies, including antiepileptic drugs.

### Patterns of Brain Injury

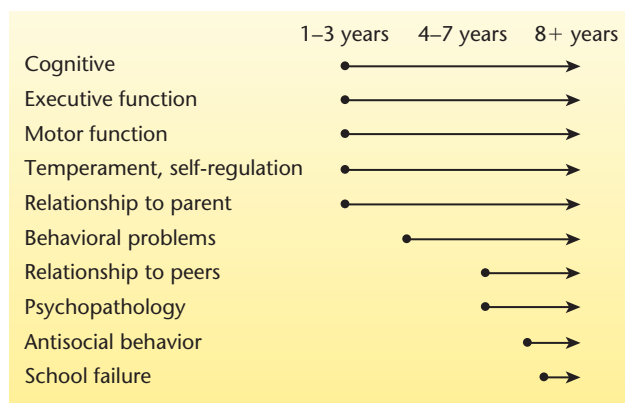

Predischarge evaluations typically include magnetic resonance and diffusion weighted imaging studies that assist in characterizing the timing and pattern of brain injury. Among infants born at term, 2 patterns of injury are predominant: basal ganglia-thalamus (BGT) injury pattern and the watershed-predominant injury pattern. BGT injury is caused by an acute event that results in near-total asphyxia. Children who suffer

from BGT injury often experience associated damage to the hippocampus and brainstem and exhibit more severe impairments than children who have watershed injuries. Watershed injuries occur after prolonged partial asphyxic episodes that compromise anterior middle and posterior middle cerebral artery blood flow, injuring the white matter and, in some instances, the overlying cerebral cortex. This injury pattern is also seen in infants whose neonatal course is complicated by hypotension, hypoglycemia, or infection. Although severe motor impairment is uncommon, children who experience a watershed injury often exhibit subnormal head growth, language delays, and behavioral problems. There is a third, less common, pattern of injury seen in late preterm and early term infants with HIE (and infants with milder encephalopathy) that involves small punctate lesions in the periventricular white matter similar to those seen in preterm infants with periventricular leukomalacia.

### Follow-up Developmental Assessments and Outcomes

Postdischarge follow-up care of infants who develop HIE requires longitudinal surveillance and assessment and early referral for intervention when delays or impairments are identified (Figure 116-4). Timely assessment of feeding, vision, and hearing and evaluation for the continued presence or late onset of seizures are essential. The infant exhibiting persistent feeding difficulties at discharge warrants early and frequent follow-up visits with careful monitoring of feeding intake, hydration status, and weight gain and growth. Early assessments between 4 and 8 months of age should focus on head growth, general health, and motor development. Initial assessments of cognitive abilities and language development should occur between 12 and 24 months of age. This facilitates early referral for early intervention because of emerging motor impairment, oral-motor dyspraxia, communication delays, and progressive or late-onset sensorineural hearing loss.

Periodic hearing testing is another important element of follow-up care: behavioral audiometry or brainstem auditory evoked response testing should optimally be performed every 6 months, until age 3 years. At a

**Figure 116-4** Timeline for assessments of neurodevelopmental outcomes. (From American Academy of Pediatrics. *Follow-up care of high-risk infants*. Pediatrics. 2004;114:1377-1397.)

minimum, follow-up hearing testing should occur at 8 to 10 months of age and between 24 and 30 months of age, with routine hearing health surveillance at each pediatric visit.

Follow-up evaluations between 2 and 4 years will assess the development of fine and gross motor function, whereas evaluations between 4 and 7 years of age assess cognitive function. Evaluation and testing between 7 and 9 years delineates learning disabilities and executive functioning, measures language and auditory processing, and assesses behavioral adaptation. Memory impairment, likely related to earlier hippocampal injury, is a common problem and includes difficulties in episodic memory (context-rich memory for events), difficulties with verbal learning and recall, and difficulties with visual recall. Semantic memory (context-free memory for facts) is less affected. School difficulties include problems with spelling, mathematics, reading, sentence repetition, and narrative memory (comprehension). Eighty percent of children with minor neurologic dysfunction and perceptual-motor difficulties have evidence of mild to moderate basal ganglia injury or more marked white matter brain lesions.

### Medicolegal Considerations

Litigation on behalf of a child with developmental delay or cerebral palsy assumed to have been caused by perinatal brain damage is a common reason for pediatric lawsuits. For pediatricians and family physicians, whether the treating physician in the delivery room or the admitting physician in the newborn or special care nursery, accurate medical record documentation is crucial. Emphasis should be placed on the use of consistent language by all disciplines. This enhances mutual understanding and reduces conflicts (inconsistencies) in the medical record. The pediatric care professionals should not characterize or evaluate (draw conclusions about) obstetric issues outside their area of clinical expertise. The source of information regarding the mother's health or medical condition should be

specifically cited in the infant's medical record, such as "The prenatal record indicates. . . ." Documentation should focus on objective information, including the neonate's findings on physical examination (description of the infant's condition), planned diagnostic studies based on the suspected diagnoses (eg, laboratory and imaging tests), and initiated or proposed treatments. Discussions with the family, including the issues discussed and any information and educational materials given that are germane to infant's care and treatments, should be documented in the medical record.

In general, the best practice is not to use terms or descriptions unless they are relevant to the infant's diagnosis, treatment, or care plan. Among terms to avoid are *perinatal asphyxia*, *intrapartum asphyxia*, *hypoxia*, *nonreassuring tracing*, *fetal distress*, *perinatal depression*, and *traumatic or difficult delivery*. There is a general recommendation that the term HIE should not be used before 1 to 3 weeks postdelivery and should only be used if there is MRI confirmation of a pattern of acquired brain lesions consistent with changes seen after hypoxic ischemic brain injury. Early MRI findings in infants with clinical signs suggestive of HIE performed when the infant is 3 to 5 days of age are helpful in providing information about the etiology (global hypoxia ischemia, focal arterial infarction [stroke]) of the brain injury.

### SUMMARY

With 1 in 5 children having a chronic health condition and nearly 1 in 12 being affected by 2 or more health conditions, pediatricians are increasingly overseeing the medical home for medically complex infants and children and working in partnership with subspecialty physicians, community professionals, and families. Survivors of advanced technologies (eg, ECMO, open heart surgery) require enhanced health and developmental surveillance throughout childhood and are prone to developmental, behavioral, and academic difficulties that are similar to those seen in early preterm infants.

## SECTION SIX

# Supporting Families During Perinatal Illness and Death

### Chapter 117

## SUPPORT FOR FAMILIES WHOSE INFANT IS SICK OR DYING

Joseph A. Vitterito II, MD; Deborah E. Campbell, MD;  
George A. Little, MD

The greatest risk of dying is in the perinatal period. For expecting families, birth is usually a moment filled with surprise, joy, and some trepidation about the responsibility of caring for a new life. With the birth of a premature or sick infant, emotions become fraught with shock, sadness, and possibly anger and grief.

Premature births in the United States have risen to record levels. Since 1981, the year the government began separately reporting premature births, the rate has increased 30%. Additionally, the rates of low-birth-weight and multiple births have also increased, significantly contributing to morbidity and mortality in the newborn population (Table 117-1).

Neonatal diseases range from prematurity to such entities as respiratory distress, birth asphyxia, sepsis, and less commonly seen conditions such as hematologic or oncologic conditions such as severe anemia, neonatal thrombocytopenia, hemophilia, hemophagocytic lymphohistiocytosis, neuroblastoma, and infantile leukemia. Box 117-1 lists the 6 leading causes of infant morbidity based on common diagnoses of infants admitted for intensive care and 5 causes of infant mortality.

Full-term newborns account for up to 40% of neonatal intensive care unit (NICU) admissions. The remainder of advanced neonatal care is for premature infants. When a newborn requires more than general newborn care, the family will also require care beyond congratulatory support and anticipatory guidance.

### BOX 117-1 Common Causes of Infant Morbidity and Mortality

#### MORBIDITY

- Birth asphyxia
- Cardiac and other congenital anomalies
- Infection
- Prematurity
- Respiratory distress syndrome
- Seizures

#### MORTALITY

- Congenital malformations (20.8%)
- Prematurity and low birth weight (17.2%)
- Sudden infant death syndrome (7.2%)
- Maternal complications (6.6%)
- Accidents/unintentional injuries (4.6%)
- Placenta, cord, or membrane complications (4%)

From Hamilton BE, Hoyert DL, Martin JA, Strobino DM, Guyer B. Annual summary of vital statistics: 2010–2011. *Pediatrics*. 2013;131:548–558.

**Table 117-1** Percentage of Preterm, Low Birth Weight, and Multiple Births

CHARACTERISTIC	PERCENTAGE OF BIRTHS				
	1990	2003	2006	2010	2011
<b>BIRTH WEIGHT</b>					
Low (<2500 g)	7.0	7.9	8.26	8.15	8.1
Very low (<1500 g)	1.27	1.41	1.48	1.45	1.44
Preterm birth	10.62	12.3	12.8	11.99	11.72
Late preterm	7.30		9.15	8.49	8.28
Early preterm	3.32		3.66	3.50	3.44
<b>MULTIPLE BIRTHS (PER 1,000 LIVE BIRTHS)</b>					
Twins	22.6	31.5	32.2	33.1	
Higher order multiples	72.8	187.4	153.3	137.6

## ROLE OF THE PRIMARY CARE PHYSICIAN

Whether providing direct care for a sick neonate, arranging for transfer to a tertiary care facility, or providing follow-up care, the primary care pediatrician (PCP) has important and unique responsibilities, especially for providing continuity in a medical home. To best support the infant and family, the PCP should be familiar with the guidelines in Box 117-2. The complete guidelines provide PCPs with specific suggestions related to initiating and coordinating acute and longitudinal care, counseling families, and, crucially, communicating with families. These combined precepts are the cornerstone for supporting families.

### Trust

Trust is the fundamental premise of an effective and dynamic professional relationship with families. Trust, in turn, facilitates communication. Transparency allows for a fluid dialogue. For the family members, informed consent establishes that the infant is, in fact, their baby.

### Communication

In the current medical model for advanced neonatal care, as in most fields of medicine, the specialist pediatrician often consults a subspecialist (ie, a neonatologist) for guidance in medical decision making. Decision making occurs with consideration of many factors and incorporates the fields of medicine, bioethics, medical sociology, and economics. In other words, physicians draw on medical education, expertise, and experience

to develop the best plan of care that suits each individual patient and family. A major part of decision making is guided by the art of medicine, which is the essence of care and decision making and which pediatricians and other physicians should consistently endeavor to refine throughout their careers. The family must be included fully and appropriately in decisions regarding their infant.

A difficulty lies with the temporal nature of information processing. In situations in which physicians may be apt to understand a disease process quickly or approach a clinical situation with volumes of clinical experience, families, with the exception of those familiar with the medical environment, are likely experiencing urgent and critical care of an infant for the first time. What a physician has learned to understand over years of training and experience, the family is struggling to comprehend instantaneously.

Communication requires sincere, forthright presentation. Shared decision making between parents or family decision makers and the infant's health care team is at the core of neonatal care, particularly when treatment outcomes are uncertain. Parents should ideally receive most information about their baby's condition from the medical team, as opposed to secondary sources. This will not only ensure that the parents/family decision makers have the appropriate information on which to base their decisions, but afford the health care team the opportunity to assist the family in articulating their beliefs, values, and preferences for their infant and family. Parents, family members, and physicians come to situations from various social and educational backgrounds. Although most families' members are not expecting to become medical experts, they deserve thorough explanations of their infant's condition and the reasoning behind decisions and care plans.

### Transparency

*Transparency* can be defined as requiring "the physician to engage in the typical patient-management thought process, only to do it out loud in language understandable to the patient." Two requirements further define this standard: providing full disclosure of the evidence and reasoning regarding proposed and alternative treatments, and encouraging and answering patient questions about proposed treatment, evidence, and reasoning.

These concepts are also applicable to delivering health care in the NICU setting. Some physicians may equate transparency with letting down a person's guard. This unfortunate view implies a defensive stance as a health care professional. Parents and physicians share the common goal of doing what is best for the infant. Without knowledge, neither party can make a decision. Without shared knowledge—that is, transparency—neither can collaborate in this decision-making process. This partnership with families forms the basis and goal of family-centered care.

### Shared Decision Making and Informed Consent

The concept of *informed consent* in pediatrics has a unique meaning. Although informed consent is generally defined as "the exercise of the patient's moral and

#### BOX 117-2 Role of Primary Care Physician (PCP) in the Management of High-Risk Newborn Infants

- Guideline 1—To make timely decisions, the PCP should be knowledgeable regarding problems that may occur in the perinatal period.
- Guideline 2—The PCP acts as an important communication link between the family and the personnel of the center providing critical care, whether or not they are both located in the same institution.
- Guideline 3—The PCP should have the expertise to assume responsibility for the acute, although less critical, care of the infant and stabilize the patient for transfer to a specialist or to specialized neonatal or NICU care.
- Guideline 4—The PCP should understand the need for proper continuity of care and be capable of providing it.
- Guideline 5—The PCP should share responsibility with the neonatologist for the development and delivery of effective services in the hospital and community for newborns.

From American Academy of Pediatrics Committee on Practice and Ambulatory Medicine and Committee on Fetus and Newborn. The role of the primary care pediatrician in the management of high-risk newborn infants. *Pediatrics*. 1996;98(4):786–788; American Academy of Pediatrics Committee on Fetus and Newborn. Clinical report: hospital discharge of the high-risk neonate. *Pediatrics*. 2008;122(5):1119–1126. Reaffirmed May 2011.

legal right to control over his or her bodily integrity," the infant patient is unable to comprehend information, exercise control, or make decisions. Although such a situation occurs with some adult patients, this inability is the state of any infant. Providing informed consent thus falls to the parents. Parents who are thrust into a new and overwhelming setting with a sick or premature infant for whom they can offer no immediate remedy may feel stripped of their rights to comfort and care for their infant. In this instance, parents must be assured of their role as part of the team and the pivotal part they have in the shared decision-making process for their infant.

In order to facilitate informed decision making on the part of the parents/legal guardians, physicians must whenever possible provide parents clear, complete, and understandable information regarding their infants' diagnoses and expected short-term and long-term outcomes. The informed consent process should offer best estimates for each potential outcome that are based on local outcome data, available assessment techniques, and the infant's condition at birth. Information regarding aspects of care that are considered experimental trials of therapy should be clearly stated to the family with discussion about the burdens and benefits of each option. Physicians should explain to the parents in clear language those medical interventions that are considered to be in the infant's best interests as well as discussing at what point they would feel uncomfortable with a nonintervention or intervention decision (depending on the infant's underlying condition and prognosis), and at what point they would seek to override parental decisions. To the degree possible, physicians should base their recommendations on published outcome data and take care to avoid a tendency to overestimate disability. It is important to note that health care professionals consistently underestimate and undervalue the quality of life for children, young adults, and their families who have experienced preterm birth or serious early childhood illness.

Physicians should provide parents with the level of information that the parents require to make the decision they think is most reasonable. When therapeutic options are perceived as having equivalent risks, or outcomes of therapy cannot be predicted, the physician should discuss all appropriate care options and offer an opinion as to the best course of action. Physicians should give their recommendation, diminishing any potential shift in responsibility to the infant's parents, thereby minimizing grief and guilt.

It is important to recognize that there are several factors that influence parental decision making. Some of these factors include the parents' reproductive history, which may involve experience of a previous preterm or high-risk infant birth, or the loss of 1 or more fetuses or babies in a multiple pregnancy. A prior history of pregnancy termination, the presence of other children from the current or previous parental relationships, prior history of infertility, miscarriage, stillbirth, or loss of a child or children all influence parental decisions and the focus of their concerns and beliefs. As a consequence, 1 or both parents may be initially more concerned about a baby's survival than his or her prognosis. Decision making may also

be affected by expectations of family life. If both the mother and the father are new to parenthood, they are less likely to have prior experience with childbirth or parental responsibilities. The parents may therefore have an idealized views of what to expect. If they have older children, parents might worry about the effect of having a new child who has disabilities. If they are already caring for a child with disabilities, they may wonder about their ability to adequately care for another child with a disability, or may think that they are fully cognizant of the breadth of care needs and can handle the additional responsibilities. They may feel obligated to take the welfare of their other children into account in decision making. Initially parental attention may be displaced towards the new child. Parents may wonder if they should involve their other children or extended family in caregiving that in some cases may entail a lifelong commitment.

The attitudes and experiences of parents and extended families towards pain, suffering, vulnerability, disability, and death, and the influence of spirituality, including religious beliefs, also influence parental decision making. The birth of a severely ill infant may undermine, strengthen, confuse, or clarify preconceived notions about family ties. Individual family members may be influenced if they have relatives or friends with disabling conditions. Parents and families oftentimes react in different ways at different points in their lives. Disagreement may occur within the family—for example, between parents, between parents and their immediate family, and between other family members. Broader social attitudes and expectations often come into play when family members find themselves directly involved in the diagnosis of a congenital or genetic disorder or decisions about withholding or withdrawing medical treatment for another family member. Issues related to maternal blame for the infant's condition, family shame at having a child with a serious illness or congenital condition, the potential for a child's marriageability, and the family's position within their community can add an additional layer of complexity to decision making and information sharing. In recent years, the Internet has contributed to a significant change in the way that people communicate and make decisions about health care. Social media provide many more opportunities for parents to seek other views and opinions on their child's condition. Families who have never met each other can communicate readily. Parents sometimes form support networks through which they may receive help or channel their experiences to assist others. Condition-specific advocacy groups may provide parents with a balanced perspective or one oriented toward a particular view. It is therefore important for the clinical team to be aware of the social media content available to families.

### **Decision Making When Parents and Physicians Disagree**

Making decisions in partnership between parents and professionals satisfies several important ethical considerations of procedural justice, personal and professional responsibility, and the well-being of those most closely involved. When parents' requests to initiate, continue, or withhold neonatal intensive care are

perceived as unreasonable, inappropriate, or clearly not in the infant's best interests, the physician has an obligation to protect the infant's well-being. This may include seeking review by an ethics committee or, if necessary as a last resort, referring to local child protective services or the courts for a case review. Court opinion is typically sought after all other options are exhausted and only when requested interventions are perceived as contrary to the infant's best interests. When consensus cannot be reached, parents and physicians both have the right to consult with the hospital ethics committee. Hospital ethics committees offer the benefits of a broader range of impartial decision makers who may act to protect infants from problematic decisions by physicians or parents. Their advice typically is limited to discussions about ongoing care, rather than emergent decisions about resuscitation.

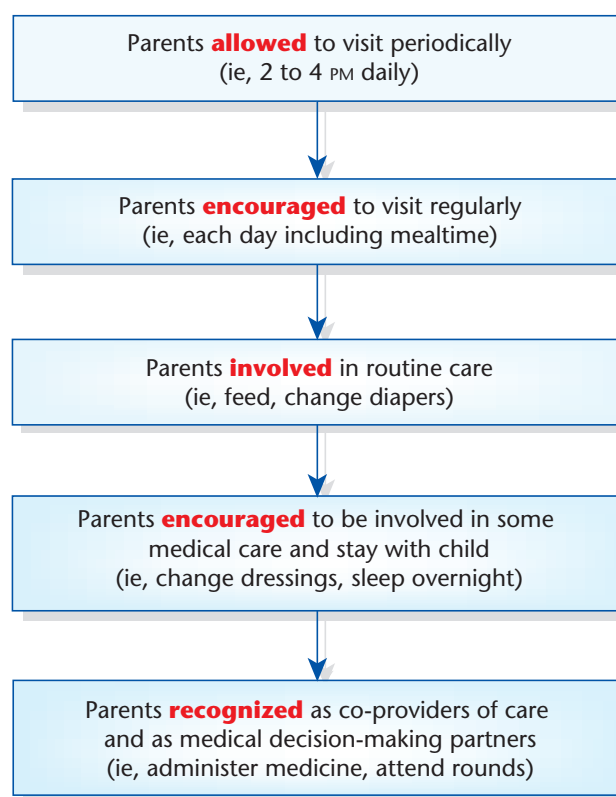

Unlike general hospital ethics committees whose members are unlikely to have extensive NICU experience, pediatric ethics committees in children's hospitals more commonly include members with expertise in neonatal medicine and the care of children with complex or disabling conditions and their families. Thus hospital ethics committees may have varying abilities to identify and weigh the benefits and burdens that parents consider in their decision making. When all agree that necessary life-sustaining treatment should be withheld from the infant, treatment should not be administered, and no civil or criminal liability should ensue. An important facet of a hospital ethics committee is the clinical ethics consultation that provides a framework for bioethics mediation. Mediation provides a process for families, and health care professionals, enmeshed in conflict as they wrestle with decisions about life and death, to articulate their beliefs, values, and preferences, and guides the physicians and caregivers in understanding and managing conflict while supporting the family's traditional and religious commitments and personal wishes. Bioethics mediation promotes balance—levels the playing field—to avoid putting some families, such as immigrants, the poor, or nonprofessionals, at a disadvantage. Mediation identifies individual interests, explores options, and helps craft a principled resolution—a consensus that identifies a plan aligned with accepted ethical principles, legal stipulations, and moral rules, and that charts a clear course of future intervention. It is also a valuable process for assisting parents and their extended families or support networks in working through internal disagreements regarding what is in the infant's best interest.

When parents refuse life-sustaining medical treatment that the physician or ethics committee feels is appropriate, the courts may appoint a *guardian ad litem* to represent the infant's best interests. The courts offer the benefits of witnesses, medical experts, a complete exposition of opposing views, and consistent reasoning across cases. However, the time required for due process is not well suited to resuscitation and intensive care proxy decision making. Court decisions involving nonintervention require clear and convincing evidence that withholding treatment is in the infant's best interests. Many courts override nonintervention decisions, restrict parental decision-making capacity, or constrain an individual's right to a natural death.

## FAMILY-CENTERED CARE

Transparency and communication are essential attributes of family-centered care. As neonatal, general, and inpatient pediatric practices aim to include family members in discussions and decision making, the concept of direct alliances with families has evolved from the paternalistic role of the physician and the permissive care role of the family. Parents and family members should be recognized as full partners and participants in care. The American Academy of Pediatrics (AAP) states that "health care providers should engage parents as co-providers and decision-making partners and seek to ensure that every encounter builds on the family's strengths, preserves their dignity, and enhances their confidence and competence." Physicians are sought for information, insight, and guidance, not for directives. In fact, all physicians involved in the care of the infant should actively seek parents' and guardians' observations and preferences for the care plan. Families should become directly involved in the general routine care of their infant, as would be done if they were at home; parents should change diapers, feed the baby, and check the infant's body temperature; parents should also record such events in the baby's bedside chart (Figure 117-1). In the neonatal realm, families may structure the day around feeding schedules or certain hospital activities, such as rounds. As they become more familiar with their infant, parents become skilled at recognizing subtle cues of illness or wellness.

The initiation of family-centered care and support optimally begins in the prenatal period. Whether the

**Figure 117-1** Evolution of hospital family-centered care.

family seeks the PCP for general counsel about the newborn period or the neonatologist for information about a high-risk pregnancy, a likely premature birth, or a suspected congenital defect, involvement should initiate the development of rapport and trust. Open, evidence-based conversation with family members that uses appropriate terminology and provides ample time for questions, comments, and expression of feelings is paramount to establishing this relationship. Parents are often interested in the basic pathophysiological features of the disease process, and clear, comprehensive explanations are important.

A multidisciplinary approach to the care of an infant and family is another vital component of support in the critical care setting. The core of family-centered care is “collaboration among patients, families, physicians, nurses, and other professionals for the planning, delivery, and evaluation of health care.” To deal with the potential reactive stages of shock, sadness, anger, and grief, teams need skills to elicit and take care of a family’s emotional and spiritual needs, as well as financial concerns, in an ongoing manner.

The core principles of family-centered care guide physicians as they assert themselves in developing compassionate collaborations with families and children. These concepts provide the backdrop in which supporting families, sharing information, and decision making can flourish (Box 117-3).

### BOX 117-3 Core Principles of Family-Centered Care

- Respect each child and the child’s family.
- Honor racial, ethnic, cultural, and socioeconomic diversity and its effect on the family’s experience and perception of care.
- Recognize and build on the strengths of each child and family, even in difficult and challenging situations.
- Support and facilitate choices for the child and family about approaches to care and support.
- Ensure flexibility in organizational policies, procedures, and provider practices so services can be tailored to the needs, beliefs, and cultural values of each child and family.
- Share honest and unbiased information with families on an ongoing basis and in ways they find useful and affirming.
- Provide and ensure formal and informal support (eg, family-to-family support) for the child and parents or guardians during pregnancy, childbirth, infancy, childhood, adolescence, and young adulthood.
- Collaborate with families at all levels of health care, in the care of the individual child, and in professional education, policy making, and program development.
- Empower each child and family to discover their own strengths, build confidence, and make choices and decisions about their health.

## NEONATAL INTENSIVE CARE UNIT ENVIRONMENT

Evidence of the importance of the environment where babies receive care has mounted. Physicians and leaders need to be proactive in designing and implementing environments that enhance recovery and long-term outcomes.

The *microenvironment* around the baby is extremely important. Physical stimuli such as sound and light affect babies in ways that remain incompletely understood, and such stimuli should be managed to prevent excesses. The *macroenvironment* within which family-centered care is provided affects physicians, families, and the infants. Physical and interpersonal considerations need to be addressed. Space and privacy for comfort, communication, and deliberation are important and subject to study, implementation, and evaluation. For example, single-patient rooms that allow family members to spend 24 hours a day with their neonate in the first or second week before discharge provide family members with the opportunity to care more expertly for their infant at home.

## SPECIAL SITUATIONS AND CHALLENGES

The care of a high-risk or premature infant presents PCPs with many unique situations and challenges. PCPs, acting in the patient’s best interest, should be prepared to incorporate the concepts of family-centered care and initiate the development of a supportive and nurturing environment.

### Consultation Before Birth

With the increasing number of extremely premature infants in NICUs, families are often facing decisions regarding the support of an infant born at the edge of viability. Although direct prenatal counseling will usually be done by obstetrical or neonatal physicians PCPs should possess basic knowledge of the data associated with survivability of, and morbidity associated with, extremely premature infants (Table 117-2, Table 117-3; see also Chapter 115, Health and Developmental Outcomes of Very Preterm and Very Low-Birth-Weight Infants). PCPs’ roles may be varied: they may initiate a consultation, offer additional support, clarify suggestions or evidence, and, in some cases, have direct involvement in resuscitation decisions and care.

Because of study limitations and the individuality of newborns, discussions focus not on absolutes, but rather on ranges of survival and quality of life. The AAP recommends the use of *nondirective* counseling while recognizing the role of direct suggestions in cases of extreme prematurity, congenital anomalies that result in a state incompatible with sustained life, or situations in which the benefits of treatment are outweighed by the associated burdens or consequences of intervention. Physicians and members of the care team must be familiar with evidence-based and local outcome data to be able to facilitate the most complete and accurate discussion.

For the family facing important decisions involving the possibility of poor pregnancy outcomes, the PCP

should facilitate a discussion that encourages the parents to explore their perception of, and ability to care for, a child with chronic illness or disability. If the pregnancy is early in gestation, then the parents may be considering termination and may seek further information, counseling, or guidance from the PCP. Discussions may explore the effect of having a child at risk of extreme hardship or early death. Similarly, parents may be guided to examine the effect that the termination of a pregnancy may have on their lives. PCPs must have insight into their own beliefs and values related to issues such as quality and sanctity of life. If the discussion about termination of pregnancy or other issues progresses beyond their level of comfort, then a referral may be appropriate.

Professional relationships formed with families with a history of at-risk pregnancy may lead to future contact when planning for another pregnancy. Proactive preconception counseling for such families (ie, interconception care) is an important part of providing comprehensive care.

### Resuscitation and Stabilization

From a practical standpoint, physicians should provide parents with a description of the delivery and resuscitation experience, including who will be present and any anticipated procedures such as intubation or umbilical line placement. Ethical principles must be incorporated into these medical discussions. The Neonatal Resuscitation Program now includes a lesson in its *Ethics and Care at the End of Life* chapter specifically designed to guide physicians with decision making and support of families.

Physicians must be careful to avoid absolutes when discussing resuscitation options, explaining the possibility of modifying decisions based on the baby's condition at birth. Nonintervention decisions based on quality-of-life or best-interests considerations are made difficult by medical and ethical uncertainties. The care team should support parents' wishes to initiate or withhold care in cases of borderline survival or significant morbidity when the prognosis is uncertain. In cases in which the prognosis is known (eg, anencephaly or newborns born at <23 weeks' gestation), resuscitation is not indicated. Parents typically prefer more aggressive care than do neonatologists and nurses, but many parents defer to physicians' judgment and do not demand resuscitation for infants unlikely to survive but not certain to die. In instances where competent and informed parents request treatment of their infant whose outcome is uncertain or prognosis is poor, a trial of therapy should be initiated or the care transferred to another physician or hospital if the physicians caring for the expectant mother and fetus do not think they should intervene. If in the prenatal period a fetal condition is identified that necessitates palliative or comfort care, then the physician should explain options and elicit input from the family. In the event parents are not clear whether to initiate care, initial resuscitation and stabilization may provide an opportunity for further assessment, offering the family and care team more data for decision making.

**Figure 117-2** Rounds in a family-centered environment encourage participation by parents. Note the mother and father (providing expressed milk by tube feeding) joining a nurse and attending physician during presentation by a medical student.

### Rounds

Parent advocates and opinion leaders have long expressed the belief that parents should be involved in all activities in which their child is discussed. Daily rounds are the primary discussion and decision-making forum in most hospital services, including pediatrics and neonatology (Figure 117-2). This time also presents an opportunity for reciprocal information and teaching. A movement toward inclusion of parents in daily rounds has recently taken place, with recognized benefits of parent involvement and satisfaction with care.

## ANTICIPATORY GUIDANCE

### Adjustment to the Neonatal Intensive Care Unit Experience

As parents transition through the emotions and realities associated with the birth of a sick or premature infant, they not only learn to cope with the news, but also begin to adapt to the new challenge of life in the NICU environment. Physicians, recognizing parents' longitudinal adjustment pattern as they assimilate the role of being a parent inside the NICU, need to encourage parents to work to maintain their lives outside the hospital. This encouragement is especially important for parents with children or other family members at home. Physicians should point out to parents that leaving the hospital as needed is acceptable; indeed, maintaining a stable and healthy family unit may be crucial. This transition is difficult for families who expected their infant, once delivered, to come home shortly thereafter.

Families with seriously ill or extremely premature infants will experience many interactions with a variety of health professionals. Their reaction has been characterized as the *model of guarded alliance*. Parents progress through 3 stages when their infant has a prolonged hospital stay: naive trust, disenchantment, and guarded

alliance. The first stage, *naïve trust*, places emphasis on the physician. It recognizes the parents' reliance, for the care of their infant on professionals with whom they are likely unacquainted. Of utmost importance in this period is referring to the infant as a baby, using the baby's name, and encouraging family members to see the baby, despite any monitors, tubes, and wires.

*Disenchantment* occurs when the infant, after a period of relative stability, worsens or fails to improve rapidly. Families of stable infants (eg, those working on achieving adequate feeding and growth patterns) may also feel as though their needs are less important than select families with a more critical infant. *Guarded alliance* occurs as parents become more comfortable expressing needs and asking questions, mainly facilitated by the trust relationships they have formed with physicians. This alliance becomes the foundation for family-centered care. In recognizing these stages, health care professionals can help normalize the family life in the unit, helping members express and prioritize needs.

For many mothers, the postpartum period produces emotional, physical, and cognitive changes. PCPs must recognize that this time requires intervention and support. Parental development in the NICU environment evolves over time as they become more accustomed to their baby, the NICU culture, and their role in this unique environment. Assuring that parents and families perceive that there is a true continuum of care for the infant is a critical facet of establishing and sustaining trust between the family and health care team. The NICU setting typically includes care provided by a large cadre of neonatal nurses, nurse practitioners, physician assistants, and respiratory therapists, rotating neonatologists, social workers, pediatric trainees (fellows, residents, interns), and medical students. In addition, families of the sickest, most medically complex infants often also interact with pediatric subspecialist consultants and surgeons, dietitians, and a variety of therapists (feeding, occupational, physical, developmental specialists). This complex system of caregiving creates the potential for parental misinformation, miscommunication, and misunderstanding about their infant's condition, complications, and treatment plans as they speak with the myriad professionals involved in their child's day-to-day care. Especially at first, adjusting to having a child in the NICU and having fellows and attendings changing service frequently can exacerbate communication problems and leave families feeling as if "no one knows their baby."

The lack of a common language or clear treatment plan as information and plans are shared can be confusing to parents and engender distrust. Various strategies can be helpful in supporting families through this challenging time: (1) identifying a primary neonatologist for communications with the family; (2) routine family meetings to provide updates to the parents, review the infant's progress and care plan, and address any inconsistencies or concerns that the parents/family has; (3) periodic discussions among the treating physicians to ensure that all participants in the infant's care are fully aware of the infant's medical issues, treatment recommendations of other team members, and to formulate an integrated, comprehensive care

plan; and (4) establishing daily care goals that can be shared with all the caregivers and family as a means to minimizing miscommunications. Engaging the baby's identified primary care provider for post-NICU pediatric care is another effective strategy that can facilitate communication and understanding. Families who have an established relationship with a pediatric primary care professional typically look to that professional for information and guidance with interpreting medical information and deciding among treatment options. The pre-existing relationship with the family can ease communication for the whole team.

The mother's partner, be it the biological father or another person, may also experience difficulty coping with the birth of a sick or premature infant. This person may have the added burden of role confusion, identifying the person's own role with the traditionally mother-baby care dyad. Physicians can aid partners by including them as part of the care team and focusing on the family as a unit when addressing the parents.

Finally, physicians should never undermine the element of hope. This act may be inappropriately viewed as a form of denial or a coping mechanism; it may also have a deep spiritual basis. After respectfully acknowledging the parents' beliefs, the PCP can emphasize the known medical facts versus what is unknown and cannot be predicted.

### Fostering Bonding in the Neonatal Intensive Care Unit

*Bonding*, the process of psychological intimacy and attachment that occurs between parents and infants, is recognized as an important component of the developmental changes that occur in families. Visitation policies, rounds, and care regimens, such as those incorporating kangaroo care, must promote the interaction of family members with the infant. Kangaroo care is a method of holding a baby that involves skin-to-skin contact. The baby, who is naked except for a diaper and a piece of cloth covering his or her back (either a receiving blanket or the parent's clothing), is placed in an upright position against a parent's bare chest. This snuggling of the infant inside the pouch of their parent's shirt, much like a kangaroo's pouch, led to the creation of the term *kangaroo care*. There are physiological benefits to the neonate as well as to the parents. For mothers and fathers, it fosters improved bonding and feelings of closeness with the babies and creates for parents an increased sense of control and increased confidence that their babies are being cared for. This is important for any parent whose infant requires specialized neonatal care, but especially so for parents whose child is critically ill or dying. Despite the known benefits of kangaroo care, there may be infants too unstable to tolerate placement on their parent's chest. In those instances, parents can be encouraged to cradle their infant on the warmer or in the infant's isolette or to use containment techniques, such as cupping of 1 hand around the infant's head with the other hand on the infant's chest or cradling the legs. The caregiving team can provide reassurance to families and assist them in determining which techniques are

most comforting to the infant. Incorporating family members into caregiving while preserving and building their sense of responsibility can help develop the optimal environment for the bonded family structure and help maximize outcome potentials.

### Siblings

Explaining the hospitalization of a sick or premature infant to a young child may prove challenging for parents. PCPs should encourage sibling visitation when appropriate and should seek opportunities to talk with children as part of routine office visits.

Sibling visitation policies vary among NICUs. Actually seeing an infant who is sick or premature may help some children understand the necessity of their parents' frequent absence. Sometimes allowing a child to simply see the hospital, describing it as the place "where mommy and daddy go every day" or "where your baby brother is living right now," may help.

As is the case with introducing a new infant into the home, children may not easily adapt to the disruption in their usual routine, or they may view the situation as a threat to time with parents. Physicians can suggest that parents keep some usual routines such as bedtime intact, or that they specifically schedule time with the child for activities. For families with chronically hospitalized infants, providing the children at home with a calendar or schedule highlighting the times the parents will be at the hospital may be helpful.

### Grandparents and Other Important Support Individuals

The role of grandparents of a sick neonate is unique and often difficult. In the family constellation, grandmothers and grandfathers are simultaneously grandparents to the child and parents to the child's parents. The grandparents' own children are, at best, under stress and, if not physically sick themselves, are often dealing with a crisis for which they have relatively little life experience.

Grandparents need special consideration, as well as guidance and care, themselves. The natural inclination to parent may be difficult to subordinate when a grandchild is in crisis. PCPs and other members of the neonatal care team need to tend to the baby and reinforce the primacy of the parents' role. At the same time, health care professionals need to provide guidance to grandparents; they can often be recruited and guided to support and assist the new parents.

Many steps consistent with family-centered care can be taken to help parents and grandparents. For example, many neonatal units permit unlimited visiting for parents and others whom the parents approve. The suggestion that grandparents might be first on the list of people to visit freely is often appreciated by all. In addition, when and if special meetings and decisions have to be faced, parents often appreciate being asked whether they would like 1 or more grandparents to be present. It is important to recognize that for some families grandparents may not be the individuals on whom the parents most rely. Their most intimate and important supporters may be other family members, a close friend, or 1 of their other children. The clinical care-giving team needs to be sensitive to each family constellation and the individuals in their lives that they

value and rely on. With parental permission, these individuals should be integrated into the child's care and support team.

### Anger

Families with infants in the NICU setting experience high levels of emotional, financial, and physical stressors that may manifest as anger. Anger can be the result of distrust, unmet expectations, or fear, or it can be the result of inherent pre-existing psychosocial stressors or medical or psychiatric illness. Acknowledging the presence of anger is the first step in assuaging discontent. Addressing concerns in a calm, private environment will present an opportunity for the physician to discern the underlying source. This step includes listening completely to all of the thoughts and feelings of the parent(s) without any defensiveness or responses until the parent(s) is finished. Commonly, this anger may be the result of a lapse or misunderstanding in communication. Admitting fault and ensuring better attention to the matter at hand may help regain rapport with the family.

In cases in which anger or disruptive behavior is a product of the family's psychopathological characteristics, social service support or psychiatric services, or both, should be involved to help counsel the family members and provide support while the family endures the hospitalization of the infant. Although the health care team must continue to communicate transparently and involve the family fully in the care of their infant, team members may be hesitant about sharing too much information out of concern of angering the family and perhaps precipitating an outburst. These situations are challenging tests of physician skills. Situations such as this often benefit from private discussion outside of formal rounds within the unit. The use of regularly scheduled family meetings may foster a calmer environment for discussions. The use of a mediation process is another option that allows families and the medical team to work together, sharing the burden of difficult and end-of-life decision making. In bioethics mediation, a member of the hospital clinical ethics team serves as an impartial third-party helping the medical staff and the family reach consensus on a treatment plan (described earlier in the section titled *Shared Decision Making and Informed Consent*).

In instances of intense verbal exchanges or physical harm or threats to patients, visitors, or staff members, the first resort is the institution's security team and contact with risk-management members. Health care professionals who feel insecure may be compromised in their efforts to care for patients.

### Death of a Baby

When resuscitation of a newborn deliberately has not been initiated or has been unsuccessful, physicians must remain supportive, caring, and professional. Whether or not they have had an opportunity before delivery to meet the family or have been involved in the infant's care in the neonatal unit, physicians need to state clearly that the infant has died. An appropriate statement would be, "I'm sorry your daughter/son has died. I am very sorry for your loss," identifying the baby by name. If culturally acceptable and comfortable,

a physical gesture (lightly touching the parent's shoulder or offering a handshake) is appropriate.

In situations in which care was withdrawn or not initiated, or if the infant's condition has been recognized as life-limiting but the parents prefer to continue care until the baby's death, parents may prefer to hold the baby while the child dies. In this instance, physicians must ask parents their wishes. The emotional act of holding the baby who is in the last moments of life is an important time for many parents to bond with and comfort the infant, and process the event. However, some families may decline to see or hold the infant for personal or cultural reasons. In circumstances in which family members cannot be present at the time of withdrawal of support or death, a health care professional may hold the infant. Nonetheless, the family should be provided with some time alone, and PCPs should offer to call support persons (eg, other family members, spiritual counselor, chaplain, bereavement specialist) as needed.

Private space for the grieving family within the hospital is important and may mean closing off the immediate area surrounding the infant's bedside. In most NICUs, suites or private rooms are available for this purpose. Finally, physicians should be present with the family in the moments surrounding the time when care is withdrawn or when an infant dies. This time is when the family will need caregivers most—if not for questions, then for emotional support. Many hospitals will offer families a memory box that contains the baby's picture and/or the footprint or a lock of hair placed with a note from the hospital and information to help the parents and other family members through the grieving process. Some parents may not want to accept the memory box immediately after their child's death, but will contact the hospital at a later date. Therefore, the memory box or mementos of the baby's life should be kept in the event that parents ask for them later.

The actual place where a child dies is of great concern to some families. Parents sometimes prefer to have a baby die in a place perceived to be closer to nature than a hospital environment—perhaps a patch of grass outside the hospital, with staff discreetly nearby. A planned death of a baby at home is an appropriate alternative. Such deaths may be anticipated to happen soon or some days or weeks ahead. Babies with conditions such as trisomy 13 or 18 might be home for weeks or months before death. Babies with shorter anticipated life spans, including those on some form of life support, might, with collaboration of medical and nursing staff, go home for a short interval. Hospital staff and physician leadership providing compassionate support and careful planning are necessary to ensure a safe transition to the home environment. This provision includes anticipating not only medical issues, but also matters such as prior notification of community services (eg, emergency response teams). Coordination between hospital and community physicians is an important general principle and is essential in these situations.

## SUPPORT FOR THE FAMILY

Caring for the family becomes an integral component of the medical care and nurturing of the infant. Psychosocial, emotional, and spiritual support for the

family are necessary elements of care since focus on the infant's quality of life and best interests frame decision making for the baby. The principles of family-centered care are interwoven in the delivery of all facets of neonatal care. These principles form the basis for an open dialogue with families that is culturally sensitive, negotiated, and respectful of the strengths, values, and perspectives that the family brings to the discussion (Box 117-3).

The health care professional should recognize and validate the parents' role and the range of experiences, beliefs and expectations, strengths, and needs expressed by the family. Family constellation and individual beliefs, values, and expectations affect a parent's ability to weather and adapt to having a premature infant or sick child. For many individuals, no greater loss exists than the death, serious illness, or severe disability of a child. Siblings may also exhibit a variety of feelings and responses that further influence a family's functioning and needs (Box 117-4). For many parents, their acute responses may evolve to

### BOX 117-4 Factors That Influence a Child and Family's Adjustment to Death

- Sudden, unanticipated death (birth catastrophe, undiagnosed lethal birth defect, or newborn illness)
  - After a prolonged illness (extreme prematurity, complex medical condition unresponsive to interventions)
  - Prenatal diagnosis of lethal or incurable condition (trisomy 13, 18, other chromosomal disorders, Potter's syndrome)
  - Stillbirth or loss of 1 or more infants in a multiple gestation
- Physical and emotional functioning of the surviving adults
- Physical and emotional functioning of the surviving siblings: age and cognitive understanding of death
- Individual personality and temperament
- Pre-existing risk factors
  - Mental illness
  - Learning and social-behavioral problems
- Family structure, functioning, and relationships
  - Quality of prior family member relationships
- Concurrent life stressors
  - Finances
  - Living situations
  - Divorce, single parenting
  - Concurrent illness in other family members
- Availability of support services, resources, and interventions before, during, and after the death

Communicating with parents of high-risk infants in neonatal intensive care. *Paediatr Child Health.* 2006;11(5):291-294.

**BOX 117-5 Strategies to Support Family Coping**

- Truth telling
  - Limits confusion, mistrust
  - Avoids unnecessary information
  - Avoids mixed messages
- Provide information simply and directly using correct words and language; euphemisms may cause more distress, although some cultures have specific preferences for acknowledging the deceased.
- Gain familiarity with cultural and religious beliefs and practices.
  - Families may have specific rituals and customs in response to serious illness or death.
  - Understand how to respond, tailor comforts, and what is within the realm of expected behavior.
  - Understand the role of religion or spirituality in family coping.
- Religion is a prime source of support and strength for many people when dealing with death or serious illness.
- Religious preferences may cause distress for individuals for whom faith has not played an important prior role or if the perceived religious tenets or proscriptions related to end-of-life decision making or withdrawal or withholding care are contrary to parental views.
- Reassure children that they are not to blame.
- Understand that children make comparisons.
  - Wishing for their life before the crisis occurred
  - Comparing their life to the lives of others
- Model appropriate responses.
  - Do not hide feelings and emotions; contain strong, dramatic feelings that might frighten, confuse younger children.
  - Find ways, if feasible, to involve children in the infant's routine while in the hospital or in funeral rituals.
  - Demystify events associated with illness, death, and burial.
- Encourage children to talk and ask questions.
  - What does the child think and feel?
  - Explore feelings about illness and death, and determine appropriateness of child's participation in the death process; visiting their dying sibling, the funeral, and burial, and sending the child away during this time.
  - Correct misinformation and misconceptions.
- Be attuned to and respond to child's own pace for sharing feelings.
  - Provide multiple opportunities for children to express their feelings; recognize that children go through developmental stages in their understanding of death.
  - Encourage expression of grief, collection of keepsakes, and sharing of memories.
  - Acknowledge and affirm children's expressions.
- Provide understanding, support, and extra guidance.
- Encourage families to seek support from other family members and friends and from the spiritual or faith community.

one of chronic or recurrent sorrow and sadness, irrespective of the child's clinical condition or level of health care need. Periods of anticipated developmental transitions or high-risk periods, such as an acute illness or the need for hospitalization or surgery, may result in the need for increased family support. Recognizing that the fears and concerns exhibited by some families may seem out of proportion to the severity of the infant's medical problems is also important. The meaning of their child's condition to the parents and family should be explored, as well as their concerns and prior experiences that may be influencing their responses.

### PERINATAL BEREAVEMENT

Parents confronting a perinatal or infant death often face common dilemmas, such as what is happening to their family; why family and friends do not understand; a sense of feeling out of balance, without boundaries or freedom; and a feeling of being atypical or different for their child and family. The grief parents experience lasts a lifetime, evolves over time, and is multifaceted. Gender differences are common in terms of the distress each parent feels. Over time, individual partner needs may change. Therefore the health care professional should recognize these differences so as to facilitate long-term adjustment for parents.

Emphasis on hope, empowerment, taking action, and parent-professional partnerships are important factors in the process of adapting and healing after a high-risk birth. Parents benefit from guidance and practical tools for their day-to-day living and decision making. The health care professional should assist the family in identifying and understanding their feelings of loss and helplessness, developing their parental identity, and managing relationships (Box 117-5). The professional must also recognize the complexities of changing expectations, parental control, death, dying, multiple births, and survival with poor, unexpected, or, in the case of multiple births, varying outcomes. If their child is critically ill, then parents must learn to cope with having to make life-and-death decisions, uncertainty regarding their infant's chance for survival, or the risk for long-term disability and understanding the realities of medical decision making when viable options may not exist (Box 117-6).

### PALLIATIVE CARE

Palliative care for neonates is an active, comprehensive approach to an infant's care and comfort and family support, from the time of diagnosis, throughout the infant's life, death, and beyond (Figure 117-3 and

Figure 117-4). It embraces physical, emotional, social, and spiritual elements, and focuses on the enhancement of quality of life for the baby and support for the family. It includes symptom management, support for the caregivers, care at the end of life, and bereavement support. Palliative care can be introduced at any point: some neonates may require palliative care from birth, others only as their condition deteriorates. A key element of palliative care is supportive care, defined by the World Health Organization as a component of palliative care that is applicable during the course of illness, in conjunction with other therapies intended to prolong life. Supportive care includes those investigations needed to better understand and manage distressing clinical complications. Families may also vary as to whether they wish to pursue treatments aimed to cure or significantly prolong life.

When prenatal diagnosis involves identification of a life-limiting condition that will lead to an early perinatal death, hospice care should begin immediately. Perinatal hospice offers a caring, supportive program of services to families who choose not to terminate a pregnancy after a prenatal diagnosis or when the timing of the diagnosis does not allow for this option. Perinatal

hospice provides information and counseling to assist families in birth planning, anticipatory grieving, and preparing for what time they may have with their infant if the child is live born. Parents who choose perinatal hospice or comfort care for their infant wish to parent their baby for as long as possible. If the infant is born alive, provide care in the hospital (mother-baby unit or NICU) or at home that focuses on how the parents want the experience to be for them, their family, friends, and their baby. This includes the opportunity to be with their baby after death and to have any ritual and keepsake activities that are important to them. Local hospice services may be engaged to support care at home for infants with life-limiting conditions who are not expected to die immediately. Referrals may include social services, religious or spiritual services, and consultation with neonatology and maternal-fetal-medicine specialists.

Palliative care for the dying neonate includes supporting the family in finding meaning in their baby's life and death. Creating a physical environment that is family centered offers psychosocial and spiritual resources, and supports the family in decision making, advanced care planning, and the grieving process.

Bereavement care begins with the infant's birth; bonding should be encouraged and families supported in their birth rituals and comfort care for their baby. Parents should be encouraged to name their infant, if this is an appropriate cultural practice for the family. The health care professional should provide the family with a private, quiet place to spend time with their dying infant and encourage them to hold, examine, and caress their infant. Families may wish to conduct cultural practices that celebrate, bid farewell, or offer protection to their infant during the dying process. Professionals may also assist families by providing resource listings that incorporate a range of media—texts, videotapes, electronic resources, and referrals to support groups—and offering information that responds to the spectrum of medical and educational information, emotional, and practical support needs of families. The professional needs to be aware of specific red flags

**Figure 117-4** Model of integrative neonatal care. (From Milstein J. *A paradigm of integrative care: healing with curing throughout life, "being with" and "doing to."* *J Perinatol*. 2005;25:563–568. Reprinted with permission from Macmillan Publishers Ltd.)

that should prompt referral of the parent for immediate medical or mental health care and assess the parent-child relationship for signs of inappropriate bonding and attachment, excessive perceived child vulnerability, and child abuse or neglect involving the infant or other children. Parents or caregivers who exhibit depressive symptoms or signs of mood disorder as well as parents who appear unable to grieve openly or whose grief is delayed or incomplete should also be referred for additional support and mental health care.

## CONCLUSION

When supporting a family with a sick or premature infant, the physician and other health care professionals must draw on a full complement of skills and resources. These situations test a physician's strength in conveying medical knowledge in a professional, clear, concise manner, while maintaining a calm, sincere, and compassionate persona. Patients, families, and health care professionals benefit from family-centered care ideals. Physicians can derive a sense of fulfillment and job satisfaction from recognizing that their efforts to help and support babies and families are effective.

- 121 Adolescent Sexuality
- 122 Adolescent Pregnancy and Parenthood
- 123 Contraception and Abortion

## Chapter 118

# CHALLENGES OF HEALTH CARE DELIVERY TO ADOLESCENTS

Richard E. Kreipe, MD

Several challenges threaten health care delivery to contemporary adolescents. Adolescence is a transitional stage between childhood and adulthood. Developmentally, adolescents share characteristics of both children and adults, often vacillating between extremes, depending on circumstances. Therefore, a health care system designed for younger individuals (who depend on their parents) or adults (who act autonomously) does not easily accommodate adolescents. The major health threats to adolescents are related to their behavior and their environments. The causes of mortality and morbidity for adolescents can be traced to modifiable behaviors more than to diseases. The US blueprint for the health of its citizens now includes Adolescent Health as a specific topic area. Focus areas include motor vehicle crashes, including those caused by drinking and driving; homicide; suicide; substance use including tobacco; sexually transmitted infections (STIs), including HIV; teen and unplanned pregnancies; obesity; and homelessness. Thus, primary health care for adolescents should focus on prevention in addition to diagnosis and management of illness. In this regard, *Healthy People 2020* includes several objectives emphasizing positive youth development such as increasing the proportion of adolescents who participate in extracurricular or out-of-school activities, who are connected to a parent or other positive adult caregiver, and who transition to self-sufficiency from foster care.

A growing body of knowledge focused on changing health-related behaviors in adolescents continues to emerge. However, the highly variable contexts of health care delivery, both the settings in which it occurs and the health care providers who render the care, represent another challenge. For example, ambulatory settings include private physician's offices, hospital clinics, school-based clinics, or private agencies. Adolescents also may receive care in free clinics that emphasize confidential services, whereas homeless youth may receive care from a mobile facility. Similarly, physicians providing these services can range from board-certified adolescent medicine physicians to youth workers. The wide variety of settings and health care providers, with little in the way of standardization or best-practice models, represents a major challenge to delivering consistently high-quality health care to adolescents. The Institute of Medicine concluded that "existing adolescent health care training across disciplines fails to address many of the health needs of adolescents." Another factor challenging adolescents is the system in which health care is delivered. Issues related to health insurance, time spent at visits, and other factors need to be addressed in a realistic manner. Although landmark health care

reform legislation is now in effect in the United States, with many positive features for adolescents, legal and practical challenges threaten many aspects of this important systems factor.

This chapter addresses each of these challenges and points to opportunities in these areas for improving health care delivered to adolescents. Improving the health of adolescents and young adults often requires strong advocacy and innovative methods. However, the challenges regarding health care delivery to adolescents are not insurmountable, if the emphasis is on the word *care*. As Peabody noted more than 70 years ago, the secret of patient care is in *caring* for the patient.

## DEVELOPMENTAL ISSUES RELATED TO HEALTH CARE DELIVERY TO ADOLESCENTS

### Puberty

Tanner observed that the only thing constant about adolescence is change. Within the realm of pubertal changes, a well-recognized sequence of events of sexual maturation exists for boys and for girls, but the timing of the onset and the velocity of the changes vary widely among individuals. Thus, healthy 12-year-old children can range from having no secondary sex characteristics to full sexual maturity. Girls are now experiencing the onset of breast development (thelarche) up to 2 years earlier than they were a generation ago. This factor is important because earlier-developing girls are at greater risk of engaging in high-risk health behaviors than those who develop later, and because girls who experience precocious sexual development may not be mature cognitively. Similarly, endogenous androgen levels (or exogenous anabolic agents) may account for some aggressive behaviors in boys. However, the psychosocial aspects of adolescence are not necessarily synchronous with each other, or with sexual maturation.

### Autonomy

The emergence of independence and autonomy, a hallmark of adolescence, also affects health care delivery. Adolescents who have not reached the age of majority (eighteenth birthday in most jurisdictions) have legal rights to seek health care without parental consent depending on several factors (Box 118-1). State laws vary on this issue, however, and thus it is important to be aware of applicable local laws.

Confidential health care tends to be sought most often for conditions that may be highly charged emotionally, such as reproductive health care. To the degree that an adolescent's right to confidential health care is honored, the adolescent's parents may feel excluded and think that their parental rights and responsibilities are being ignored. Health care providers, especially family practitioners, family nurse practitioners, and physician's assistants who provide primary care for both adolescents and adults in a family, may be caught in the middle of this conflict. Determining what is in the best interest of the adolescent

**BOX 118-1 Factors Permitting Health Care for Minors Without Parental Consent**

- Marriage
- Military service
- Bearing a child
- Living independently (emancipation)
- Reproductive care
- Mental health or substance abuse evaluation
- Life-threatening emergency care (until parents are contacted)
- Local laws governing legal status

may be difficult in such situations. A balanced approach, honoring the rights and needs of both adolescents and parents, is most productive. Nonadherence to treatment, especially for chronic illnesses such as diabetes, HIV infection, or cystic fibrosis, often emerges during adolescence as a manifestation of a struggle for autonomy. Adolescents may not want to be told what to do, or they may use the disease as a means of exerting control in conflict with parents.

**Cognition**

Nonadherence to a treatment regimen may be related to cognitive limitation because of the concrete, operational nature of adolescents' thinking. For example, a 15-year-old with pelvic inflammatory disease might be encouraged by a physician to complete a 14-day course of antibiotics to prevent infertility. After taking the medication for 2 days, she might stop treatment because she feels better. However, she might also interpret the warning about infertility after an insufficient course of treatment to mean that she no longer needs to use birth control. A better method to increase adherence would be to warn about the possibility of chronic pain or internal scarring if she does not complete treatment. These complications are concrete and immediate realities that may have greater meaning to the patient than warning about a possible future, abstract concept such as infertility. The delivery of health care to adolescents should take into consideration the cognitive functioning (including the literacy level) of each patient and adapt education and interventions accordingly.

**Identity**

Identity development, sometimes characterized as the "essence of adolescence," can present a challenge to professionals delivering health care to patients in this age group. As the major task of adolescence, identity development generally occurs in the context of peer groups, which can have either health-promoting or health-threatening, risky behaviors. The latter behaviors may predispose individuals to STIs, unintended pregnancy, violence, or substance abuse, and may also make obtaining the history extremely difficult. For example, if a girl has been forbidden by her parents to see her boyfriend, she may deny sexual activity with him; or if a boy is a member of an athletic

team known for drug use, he may not be willing to admit to substance use. Similarly, a boy experiencing emerging homosexuality may have numerous concerns related to this aspect of identity and behavior but not be able to address them unless specifically asked about sexual orientation by a physician. Thus, the developmental aspects of adolescence itself present significant challenges to the delivery of health care in several domains.

Not all identity developmental challenges represent barriers to the delivery of care, however. Normal adolescents focusing on their own identities may be very self-centered or egocentric. Instead of viewing this as a narcissistic shortcoming, the physician can use it to the patient's benefit by providing authoritative advice to help the adolescent to take control, rather than an authoritarian prescription of what must be done. Alternatively, adolescents may modify their physical appearance as a personal statement reflecting their identity. Multicolored hair, body piercings, tattoos, and clothes all relate to the emerging individual's sense of self (even if the person assumes an appearance that is remarkably similar to that of peers). For physicians, the challenge is to continue to respect the person, regardless of how unusual the adolescent may appear, and to identify the positive qualities and assets of each adolescent, as described by Ginsburg in a strength-based approach.

**MORBIDITY AND MORTALITY IN ADOLESCENTS**

As illustrated in Box 118-2, most mortality and morbidity in adolescents is generally related to behavior and potentially preventable.

An effective means of preventing many of these conditions, however, remains elusive. Because adolescents are generally healthy, adolescent health care should focus on behavior, knowledge, and attitudes, rather than on illness. The conditions affecting the health of adolescents are not readily preventable, may be resistant to treatment, or may require interventions that physicians are unable to provide. Therefore physicians need to involve other segments of society, such as social workers, educators, and law enforcement individuals, to assist in providing an environment that encourages healthy behaviors.

Given the nature of health problems facing adolescents, physicians may feel unprepared to address either the problems or the adolescents who contend with them. An analysis of a US national ambulatory dataset found that counseling regarding nutrition, exercise, STIs, or birth control was 2 to 3 times more likely at an acute visit than at a well visit, which is intended to include such counseling. Thus adolescent health care providers require a high degree of flexibility and willingness to use each encounter with adolescents as an opportunity to provide anticipatory guidance. Moreover, physicians benefit from training and experience related specifically to the care of adolescents. This training and experience is available through publications, continuing-education services, and programs by professional organizations such as the American Academy of Pediatrics ([www.aap.org](http://www.aap.org)),

### BOX 118-2 Major Causes of Mortality and Morbidity in Adolescents and Young Adults

#### **Mortality** (causes of 75% of deaths)

- Motor-vehicle crashes
- Homicide
- Suicide

#### **Morbidity**

- Mental health (depression, anxiety)
- Violence-related injuries
- STIs (including HIV)
- Unintended pregnancy and its complications
- Substance use/abuse
- Eating disorders and obesity

the Society for Adolescent Health and Medicine ([www.adolescenthealth.org](http://www.adolescenthealth.org)), and numerous universities that provide hands-on or distance-learning opportunities in adolescent health.

In response to the need for greater efforts at preventing morbidity and mortality among adolescents, different comprehensive preventive strategies have been developed, most notably the American Medical Association's *Guidelines for Adolescent Preventive Services* (GAPS) or the American Academy of Pediatrics and Maternal and Child Health Bureau *Bright Futures Guidelines* ([brightfutures.aap.org](http://brightfutures.aap.org)). These resources structure both initial and follow-up health supervision visits by providing paper forms that adolescents and parents complete and providing specific questions that physicians can use in assessment and management.

## CONTEXTS (SETTINGS AND PROVIDERS) OF HEALTH SERVICE DELIVERY TO ADOLESCENTS

### Outpatient Settings

As health care expands to include preventive adolescent services, the settings in which health services are delivered to adolescents have appropriately expanded beyond the physician's office or the hospital bed. A wide variety of service settings and an even wider variability of service providers are available. For example, within the category of private office, the physician might be a pediatrician, internist, or family physician, each of whom will have different training in adolescent health, ranging from an optional elective to a 3-year fellowship in adolescent medicine. In addition, nurse practitioners and physician's assistants often provide health care to adolescents, depending on the setting (eg, college- or institution-based care) and geographic location.

School-based clinics offer many advantages, most notably convenience, ready access, and the ability to minimize school absence. Because schools represent a focal point of youth activity, full-service schools that offer education, health services, after-school activities, and family services are attractive. This model has

special advantages for inner-city communities that may offer little in the way of quality health care or safe out-of-school activities to their residents. The challenge is to get the community invested in the program; this requires a commitment by school and community leaders to ensure the program succeeds. Many federally qualified community health centers (FQ-CHCs) provide excellent health care for underserved adolescents, both urban and rural, precisely because they require active engagement by the community that they serve.
